The following case of acroparesthesia is more or less typical: A retired sea captain of sixty, robust and vigorous, with hair partly gray and with a florid complexion, complained of a burning or stinging sensation in the outer three fingers of both hands, most marked and often extremely painful in the ball of the left thumb. This had come on gradully about two years previously and had persisted constantly, although only very severe at intervals. These intervals were apparently neither influenced by the weather nor the diet. He drank on an average of 2 ounces of whiskey or brandy a day and smoked three or four cigars. He had once given up drinking and smoking for over a month without relieving his symptoms. The discomfort in his thumb was usually worse at night and he would often rise and soak his hand in hot water, which gave temporary relief and aided him in getting to sleep. He said he had visited "over sixty doctors," including "several London specialists." Gout and rheumatism had been the usual diagnosis. Acroparesthesia was a "new one" for him. He had "tried all kinds of physics and systems" without relief and had finally come to the conclusion that "all doctors are fools." During his life he had experienced much exposure from cold and dampness, but had never been ill as far as he remembered. There was no history of any past cardiac, pulmonary, hepatic, renal or intestinal symptoms, or of syphilis. He confessed to having been a "steady but sober" user of whisky and brandy for an indefinite period. Physical examination showed a well-nourished body, the muscles fairly well developed and the skin beginning to lose its elasticity. The peripheral arteries were only moderately sclerosed. Eyesight was good except for a little hypermetropia; no Argyll-Robertson pupil. Lungs apparently normal, liver and spleen not felt, abdomen negative. Heart sounds good, except for moderate accentuation of the second aortic. There was no evidence of gouty or rheumatic trouble. The urine showed no albumin and no sugar, and was otherwise normal, save for two or three hyaline casts. The knee and elbow reflexes were present, but feeble. No tremors; no Rhomberg's sign. The involved fingers showed nothing peculiar except possibly a little abnormal pallor. There was lessened sensation to touch and pain over the right thumb and to a limited extent over the other affected fingers. The sensation of heat and cold were not tested. There were no motor symptoms evident; the grip was strong.

The treatment consisted of a full diet and a lessened consumption of alcohol. Sprudel salts were given twice daily and local douches of hot and cold water four times a day. Later, an irritating ointment of tincture of capsicum was added. These measures at first appeared very beneficial, but a return of the symptoms in full after a few months made it appear as if the relief had been a regular feature of the affection. The patient declared that he could get along very well with the other fingers if only the pain in the ball of the thumb would cease. The best I could suggest was partial excision of one or more cutaneous nerve branches which supplied this finger. Soon after, the patient returned to his home in England. Two months later I had a letter from him. He stated that he had followed instructions and had had "a piece of nerve cut from the thumb" one month before. He had experienced no pain in this mem-

her since, although, he wrote, "my thumb feels so dead all the time now, that I sometimes wish a few old tinglings would come back and wake it up."

Two excellent accounts of acroparesthesia, translated from the German, may be found in Strumpell's text-book, and in Cassirer's article in "Modern Clinical Medicine."

BERBERINE.

By WILLIAM FRANCIS WAUGH, A.M., M.D.,

CHICAGO, ILL.

PROFESSOR OF THERAPEUTICS, BENNETT MEDICAL COLLEGE (MEDICAL DEPARTMENT LOYOLA UNIVERSITY).

Plants have been applied as medicines from time immemorial. Of many we know to-day no more than did Hippocrates; of many others we know but the merest surface indications. The day will come when the eye of modern science will be directed to the drug plants, a new study will be made under modern methods, and we shall find many a gem of priceless worth in this neglected field.

As an example of what awaits the investigator, take berberine. This alkaloid is found in many plants of various families. It is derived commercially from hydrastis canadensis, but the increasing scarcity of that plant must soon direct the extractor of active principles to berberis, menispermum, xanthoxylon, and other plants, from which a plentiful supply can be secured. It is one of the economic advantages of the alkaloids that all portions of the plant containing them may be utilized, instead of wasting all but the official part.

By the standard works on therapeutics berberine is ranked as a simple bitter. All the experimentors have given us is that, in large doses, injected intravenously in dogs, berberine causes paralysis of the posterior extremities and a few other highly undesirable things. Judging by their results, there is no place for berberine not amply filled by quassia.

Our great difficulty is that nothing like a scientific study has ever been given to berberine. We get a bit of misinformation and it is handed down for generations, nobody taking the trouble to prove or disprove it, until it becomes fixed as a part of the general acceptance of our profession. For example, the legend as to the superiority of the second year's leaves of digitalis, recently proved false.

When we turn to the field of clinical research we find some curious observations. Plants containing berberine have been lauded as causing contraction of a malarial spleen. Others containing berberine have been suggested as contracting the uterus, inducing abortion, or checking the growth of uterine fibroids. The berberine plants have been given to combat flatulence, dilatation, and ptosis of the stomach and intestine.

Here are three distinct applications made of plants that possess one thing in common, that they contain berberine. The three maladies mentioned have this common feature, that the effects obtained indicate contraction of the connective tissue elements of the parts involved. There is a third common feature that in each the remedy was administered in *moderate doses for prolonged periods*. Gathering up the threads, we find ourselves justified in advancing this proposition as a working hypothesis: That berberine, given in moderate doses for a prolonged period, specifically induces contraction of relaxed connective tissue.

Assuming this to be true, we have in berberine a remedy for this connective relaxation in any disease where this pathological condition appears as a factor. Beginning with enlarged spleen, I have for years advised that berberine should be administered in doses of a centigram seven times a day, gradually increased to three centigrams, and continued for six to twenty-four weeks. At the same time quinine arsenate is given, six centigrams a day, to act upon the parasites forced from the splenic cloisons into the circulation. The contents of the bowels are also kept soluble; and disinfected by a sufficiency of sulphocarbolate of zinc. Should there be any reader who does not realize the value of this latter feature in treating malaria, I would advise him to go to the malarial belt next fall, and make observations at first hand. From this seat of paludal war I have many satisfactory reports on this method.

My opportunities for observing uterine fibroids treated by berberine have been too few to justify me in more than merely mentioning the plan, as a suggestion in cases where operation cannot be made.

In gastroptosis, enteroptosis, displaced kidneys, prolapsus uteri, dilatation of the stomach and bowels, pendulous relaxed belly, and other cases, we see relaxation of the connective tissue framework or supports as a factor. In all these I have employed suitable mechanical support, which does not alone effect a cure, and have given berberine, which adds the one needed element to convert palliation into cure. It is hardly necessary to add that in treating dilatation of the stomach a rigid dietary régime is absolutely necessary.

So far as my observations go, they have given support to our hypothesis. I have no statistics to submit, not even a solitary case record. Statistics may be made to support anything, even the anti-vaccinator. They are only of value after a remedy has been put to general trial, when the use it proves to have for the profession at large may show its true worth, and not the applications made by a single individual with possibly exceptional circumstances. The experience of Mayo's anesthetist with ether is certainly not that of the general practitioner.

I believe berberine, given in daily doses of one to three grains for not less than six weeks, tends to induce contraction of relaxed connective tissue, and may be advantageously applied in every malady where that pathological element is a factor of importance.

Venesection in Eclampsia and the Preeclamptic State.—M. Potocki advocates the use of venesection in all albuminuric cases in pregnancy in which convulsions are threatened or have begun. If a liberal amount of blood is removed, *i.e.* 600 to 1,000 grams, relief is at once obtained. The use of chloroform and chloral as sedatives in convulsions has a bad effect on the liver and kidneys, which should be able to remove the poisons from the organism. Jaundice is frequent after the long use of chloroform in eclampsia, and even after laparotomies. Increased arterial tension is one of the most important symptoms of the eclamptic or preeclamptic state, and remedies should be administered for its relief. Often the congested, violet face of the eclamptic suggests the necessity of venesection. The author has used venesection in a number of preeclamptic cases with the result that the headache and agitation were relieved and the patients were delivered normally of living children. None of the patients died. Tarnier states that placing the patient on a milk diet for a week will relieve the albuminuria. But one cannot always wait a week for this remedy to act and convulsions may occur before the week has elapsed.—*Journal de Médecine de Paris.*

JUSTICE TO THE MARINE-HOSPITAL SERVICE.

After many years of patient waiting the officers of the U. S. Public Health and Marine-Hospital Service, will soon, it is hoped, obtain from a grateful but not over liberal country, a recognition more substantial than editorial encomiums, of the value of their labors in the cause of public health. Up to within four or five years the medical officers of the Army, of the Navy, of the Revenue-Cutter Service, and of the Marine-Hospital Service were on a practical equality as regards pay. This pay was, however, so inadequate in view of the character of the service demanded and so far below the amount that men of equal attainments could earn in civil practice, that the services began to suffer for lack of candidates. To make up for the diminishing numbers in the regular services civilian physicians were hired, but as these "contract surgeons" were accorded no rank and had no assurance of permanence in the service, their employment was only a makeshift and was far from satisfactory. Some of them were good surgeons, but they seldom became good military surgeons, and the services continued to suffer. Finally Congress was led to recognize the magnitude of the evil and passed efficiency bills for the Army, Navy, and Revenue-Cutter Service, raising the pay of medical officers in each grade of these services about $500 a year. The Marine-Hospital Service was, however, ignored, the efficiency bill in its favor being lost. The result of this was to embarrass the Service greatly, not only in its endeavor to get new men, but even in its power to retain its old officers. It is well known to the medical profession, if not to the public, that the Marine-Hospital Service has recently lost some of its most capable officers, men of the highest attainments as scientists and sanitarians, with a practical training which only years of service could give. These men had families to support and children to educate, and they could not, in justice to themselves and their families, refuse positions of honor and far greater profit offered to them in other fields.

To show under what substantial disadvantages the officers of the Marine-Hospital Service labor we may compare their pay with that now given the medical officers of equal rank in the Army or the Navy, the two latter being practically the same. In the Army the pay in the different ranks is $6,000, $5,000, $4,500, $4,000, $2,400, $2,000. In the Marine-Hospital Service the pay is $5,000 ($1,000 less), $4,000 ($540 less), $3,500 ($1,000 less), $3,500 ($500 less), $2,000 ($400 less), $1,600 ($400 less). In this comparison no account is taken of the commutation rates and allowances for fuel and lights, in which the discrepancy is great. On first thought, one might say this difference in pay and emoluments was justified by the fact that the members of the medical corps of the Army and Navy must risk their lives in time of war. But one forgets that the officers of the Marine-Hospital Service are constantly at war with disease and risk their lives daily. Much is said, and justly, in praise of the heroism of the Army yellow fever commission under Major Reed in Cuba, two of the members of which died of the disease or its sequelæ. But it should not be forgotten—perhaps it is not known—that fourteen of the officers of the Marine-Hospital Service have contracted yellow fever in line of duty and six have died therefrom; others have suffered from typhoid fever, tropical dysentery, cholera, and typhus fever—all in the day's work. When yellow fever visits New Orleans, the Marine-Hospital Service is called upon to fight it; when the plague invades San Francisco, again the officers of the Marine-Hospital Service are sent to repel it. The officers detailed to this dangerous duty go as promptly and as bravely to the scene of warfare with disease as do the medical officers of the Army and Navy to battle. The Army and the Navy are necessary to the safety of the country and the medical officers of these services are necessary to preserve the health of the defenders of the nation, but the officers of the Public Health and Marine-Hospital Service are even more immediately and directly necessary to the health of the community than are their colleagues in the military branches of the public service. They have charge of all but four or five of the quarantine stations of the country, certain of them are on duty constantly in disease-infected ports of Europe and the East to inspect passengers embarking thence for the United States and to warn quarantine officers here of the possible invasion of epidemic disease. The Service maintains a laboratory for the study of disease and to maintain the purity and efficacy of vaccine virus and antisera. In fact, were this Service to be crippled by the loss of trained officers and inability to obtain as recruits capable men of sound medical training, the health of the country would be greatly imperiled.

Fortunately Congress has awakened to this danger and has wisely taken steps to avert it. A bill to raise the pay of the officers of the Public Health and Marine-Hospital Service to a parity with that of medical officers in the Army and Navy has passed the Senate and has been introduced in the House of Representatives. It was referred to the Committee on Interstate and Foreign Commerce, which has reported it without amendment and with a recommendation that it pass. It is now in the Committee on Appropriations and if it secures the approval of that committee will undoubtedly be approved by the House. It hardly seems possible that it can fail to pass the Committee, for it involves a total increase of expendi-

tures of only about $100,000—a very small sum to insure the maintenance of the present efficiency of the Service.

This is a matter of vital concern to every citizen of the Republic, and we as medical men, knowing especially the dangers to which our country is constantly exposed by disease within and without, and knowing also that one of our greatest safeguards lies in the efficiency of the personnel of the Public Health and Marine-Hospital Service, should individually and collectively urge upon our representatives in Congress the necessity of strengthening this arm of the public service by an act of simple justice to a body of earnest and self sacrificing workers for the common weal.

A NEW THEORY OF NEPHRITIS.

In spite of much experimental work and clinical observation the pathological physiology of nephritis has not yet been cleared up. The great differences in the urinary changes observed in the different types of the disease, the presence or absence of edema, the accompanying cardiovascular changes, all have remained almost as obscure in their causation as at the time when Bright wrote his classical descriptions of the kidneys found by him post mortem in patients with nephritis. Every new theory of the disease, however strange to our ears, must therefore be seriously considered by the medical profession, and one such theory has recently been put forth by Martin H. Fischer* in an essay which was awarded the Cartwright Prize of the Association of the Alumni of the College of Physicians and Surgeons in this city.

Fischer's work is founded upon the study of colloids and their behaviour under different experimental conditions, comparable to those under which the kidneys perform their work in health and in disease. The colloids involved in nephritis, according to Fischer, consist in the main of the blood, which is essentially a suspension of colloids in which are floating fairly solid jelly-like structures or cells; of the "urinary membrane," which includes all the structures that lie in the kidney between the blood on one side and the urine on the other, and of the urine, which normally is a solution of salts and is not colloid in nature, but whose colloid content rises in nephritis. Albuminuria, that chief urinary change in nephritis, has always been held to be due to the escape of the albumin of the blood through the diseased kidney, or what Fischer terms "the urinary membrane." To Fischer, however, albuminuria is something quite independent of the blood; its albumin is derived not from that tissue but from the kidney itself, whenever circumstances arise that favor the transition of the gelatinous colloids of that organ to the soluble state in which albumin is found in the urine. These circumstances may arise in different ways, but their chief mark is the fact that they produce an increased amount of acid in the kidney and thus favor the solution of its colloids. This production of acid is to Fischer the alpha and omega of nephritis, the cause of albuminuria, the cause of the morphological changes in the kidney, the cause of the production of casts, of the variations in the amount of urine, and of the dissolved substances secreted by the kidney. While the normal kidney is not acid in reaction, a kidney of nephritis, as shown by microchemical methods, becomes acid, and takes up corresponding dyes. Sections of freshly excised kidney take up such stains but very slowly, and very slowly give up albumin to the solution in which they are immersed. But let a trace of acid be added and all parts of the kidney become deeply stained, and the albumin content of the surrounding fluid is quickly increased.

The morphological changes in the nephritic kidney are likewise explained by the accumulation of acid; it leads to the absorption of water by the individual cells, to the "edema" of them, and a consequent increase in the size of the kidney; it produces changes in its colloids and consequent "cloudy swelling" of the cells; it leads to the filling of the uriniferous tubules by the dissolved colloids and the consequent appearance of casts in the urine. Only subsequently the damaged tissues are replaced by connective tissue which slowly takes up the space of the parenchymatous cells, slowly contracts and leads to the appearance of the later stage of the nephritic kidney, namely, the small or atrophied organ.

This, in brief, is Fischer's thesis and it is supported by numerous experiments and by clinical observations of patients on whom treatment founded upon his theory of nephritis has been tried. There are many flaws in his argument. It is far from being proved that experimental nephritis produced in animals is comparable to the nephritis in human beings. It is difficult to follow his argument, when he attempts to show that acidosis in such conditions as diabetes may not result in nephritis because of the difference in the acids present, both in quantity and quality, from those responsible for the phenomena in nephritis. It is still more difficult to wave lightly away all the evidence we have of the important rôle of salt-free diet in the reduction of nephritic edema and accept instead Fischer's methods of treating edema by intravenous or rectal administration of concentrated solutions of alkalies and salt, etc., etc. Yet his theories of the "principles" of nephritis are plausible enough; their truth or falseness should be easily established by well-planned experiments in the laboratories and careful observations in the wards. Nephritis is too important a chapter in human pathology to excuse any disinclination to test out any new and reasonable theory of its etiology, disinclination founded mostly on the well-known tendency of the human mind to cling to old beliefs and explanations rather than to accept novel and revolutionary ones.

* Nephritis. An Experimental and Critical Study of its Nature, Cause, and the Prinicples of its Relief. By Martin H. Fischer, Eichberg Professor of Physiology in the University of Cincinnati. Price $2.50. New York: John Wiley & Sons. 1912.

THE MENTALLY DEFECTIVE AND INSANE AMONG IMMIGRANTS.

The danger to society which exists from the mating of the unfit has long been recognized in a general way, but it is only since the new incentive which the revival of Mendelism has given to the study of

heredity that we are beginning to have light shed upon the dark places of this much involved and complicated problem.

As illustrating the inheritance of a bad mental twist from one ancestor alone, Conklin* cites the case of a young man of good family who, after his discharge from the Continental army, mated with a feeble minded girl in New Jersey. From this union came a feeble minded daughter whose blood can be traced in 480 descendants; of this number 143 were distinctly feeble minded. The young man whose illegitimate escapade started this long strain of defective stock subsequently married a normal woman of good ancestry. From this marriage there were eight normal children from whom a total of only 365 descendants have arisen. Of the 365 there are no feeble minded and only one insane. This family history bears out the belief that feeble minded stock not only tends to reproduce its kind, but also that it is more prolific than the normal. Thus the danger from the introduction of tainted blood into the social organism assumes a twofold importance, and fully warrants the alarm which is felt by the immigration restrictionists over the number of alien insane and defectives which are annually increasing our already sufficiently large stock of these classes. The law provides for the deportation of "all idiots, imbeciles, feeble minded persons, epileptics, insane persons, and persons who have been insane within five years previous, or persons who have had two or more attacks of insanity at any time previously." Until 1905 not more than 35 immigrants were denied admission on account of insanity in any single year, but since that time, and without any especial change in the law, the number has arisen to nearly 200 annually, and nearly as many defectives as insane persons have been excluded.† It therefore appears that the effectiveness of the law dealing with the exclusion of the insane and mentally defective depends entirely upon the means provided for its enforcement. These means must necessarily reflect public opinion. Given a popular law, and its enforcement is rigidly observed, whereas the law that does not meet with public favor is more honored in the breach than the observance.

The signs of the times point to an increasing desire on the part of all concerned to see this phase of the immigration restriction law still more rigidly enforced, but as pointed out in the annual report of the Commissioner General of Immigration, there is an inadequacy of time and facility for its proper enforcement. This means that the corps of examining physicians and interpreters is not sufficiently large, and that there is no practicable way in which all arriving aliens can be detained for inquiry into their mental condition. To overcome one of these difficulties a bill was introduced into the Senate last summer in which it was proposed that physicians be placed upon immigrant ships at the time of their embarkation for this country. In this way it was thought that the steerage passengers could be kept under observation for the period of their voyage, and thus the number of detected insane and mentally defective might be materially increased. That the problem is worthy of the best thought of the administrative officers at all immigration stations is evidenced by the ever-increasing testimony to the prevalence of insanity and feeble mindedness among the alien population. Thus in New York State, where the influence of the foreign born in every sphere is most keenly felt, it has been shown that immigrants in the proportion of 1 to 250 of all who come to that state are admitted to the psychopathic wards of Bellevue Hospital and Kings County Hospital, and to the New York State Hospitals during the first year of their arrival.

Relative to the prevalence of mental deficiency among alien children, recent census statistics show that the progeny of aliens or naturalized citizens are responsible for 30 per cent. of the feeble minded in the general population of the United States. The researches of Dr. Isabelle Smart, who has long been prominently identified with the work of educating "backward children" in the New York public schools, also bears out the general impression that the immigrant contributes more than his proportionate share to this class. But even though the alien population should contribute only its proportionate share to the insane and mentally defective, the methods for the detection of these classes before the final landing should be increased to the highest point of efficiency; for after all, the question is not so much one of determining the exact amount of increase of tainted stock from foreign blood as it is to prevent all such increase from every possible source.

*W. J. Conklin, "The Mating of the Unfit," a Study in Eugenics.

†F. M. Salmon: N. Y. State Hospitals Bulletin, November, 1911.

THE ROLE OF GARDEN VEGETABLES IN THE DISSEMINATION OF TYPHOID FEVER.

Whatever the medium by which the typhoid fever germs may be spread, the question of their viability outside the human body is of primary importance. This problem has been worked out by many investigators so far as the usual media of water, milk, and soil are concerned, but until comparatively recently very little attention has been paid to the rôle of raw foodstuffs, such as fruit and vegetables, in conveying infection which they may have acquired during cultivation.

In order to increase our knowledge on this phase of the subject, R. H. Creel* carried out a series of experiments in raising radishes and lettuce on soil which was infected with the *Bacillus typhosus*. This infection was accomplished subsequent to the seeding, but prior to the appearance of the plants. As a result of this work he found that plants would take up with them on their leaves and stems the microorganisms which they encountered as they pushed their way through the infected soil. Furthermore, it was found that *Bacillus typhosus* could be recovered from the leaves and stems of plants that were to all appearances entirely free from adhering particles of dirt. In order to determine how far natural rainfall might be expected to free the vegetables from the organism, a leaf of lettuce from an infected bed was repeatedly washed with sterile water, and then the leaf, in an almost

*Public Health Reports, February 9, 1912.

macerated condition, was rubbed on an Endo plate culture. This experiment yielded positive results, and seems to warrant the conclusion that ordinary cleansing by rainfall, or under the kitchen faucet, will not free the infected plants from the germs. Furthermore, under conditions most unfavorable to the growth of *Bacillus typhosus*, the infection lasted at least thirty-one days, which is a period sufficiently long for the maturity of quick-growing varieties of lettuce and radishes.

In view of the results of his experiments, and considering the fact that other observers have proven that the life of *Bacillus typhosus* in soil may be prolonged to sixty or even seventy days, Creel considers that the fertilization of garden soil by human excreta assumes a two-fold importance. First, the vegetables, such as lettuce, radishes, and celery, may directly convey the infection, and second, the soil may serve as a reservoir for bacteria. Drainage from such germ-soaked areas may carry the microorganisms to streams of water, and thus keep up the infection much longer than if the water were directly infected.

In view of the already well-known dangers incidental to the exposure of night-soil in such situations as to render it easily accessible to the house fly, it would seem that these experiments serve to add another strong argument against the use of human excreta as a garden fertilizer.

HYGIENE OF THE MOUTH.

The vital importance to a race and nation that its members should have good teeth and a healthy condition of the mouth is being emphasized more and more every day. William Hunter, a well-known British physician, has been especially persistent in preaching the godliness of cleanliness so far as the mouth is concerned. To neglect of the hygiene of the mouth he attributes a large number of serious diseases, both local and general: in the mouth itself dental necrosis in all cases, gingivitis, and stomatitis of every degree of intensity, suppuration around decayed teeth and deposition of tartar; in the jaws, periostitis, alveolar abscesses, osteomyelitis, maxillary abscess; in parts adjacent to the mouth, tonsillitis, pharyngitis, otitis, glandular enlargements, etc. Gastric catarrh and anemia are also laid to the charge of the unclean mouth.

Goadbey, in a recent Hunterian Lecture, referred to the menace of neglected mouth hygiene in the following terms: "Lowered vitality favors the vegetation of microorganisms in the mouth, these attack the teeth and the diseased teeth still further lower the vitality so that a vicious circle is established. The efforts for the prevention of caries will serve equally well to prevent those ill effects to the general system which proceed from unhealthy conditions of the teeth. The dental surgeon and medical practitioner alike must strive after the ideal, which to vary an old saying, should be *dens sana in corpore sano.*"

Various medical writers in all countries have laid stress recently on the enormous importance of mouth hygiene. In the first instance the teeth themselves should be cared for, all decayed teeth should be removed, and the mouth should be kept clean and wholesome by intelligent brushing. But it is not enough in order to guard against disease simply to keep the mouth clean, although in itself this is an essential step in the right direction. The employment more or less frequently of an efficient disinfectant is indicated. The fact must be borne in mind that the mouth is the main avenue for the entrance of a large number of infections.

Difficulty of the Diagnosis of Methylism.

Our knowledge of methylism is due largely to the labors of ophthalmologists, who, when their aid is sought for sudden amaurosis or blindness, have learned to associate such conditions with the possible consumption of wood alcohol in some one of half a dozen forms. But in only a certain percentage of cases does vision suffer, and then only when actual optic neuritis has developed. It is hardly conceivable that any substance is so peculiarly neurotropic as to attack invariably the optic nerves alone, to the exclusion of other nervous tissues. In the absence of ocular symptoms is there any other phenomenon to suggest methylism to the exclusion of many other affections? If the matter vomited or washed from the stomach be tested for methyl alcohol, it would appear that while certain tests result positively others may give negative results. The odor of acetone in the stomach contents and urine is not conclusive. That in sudden death from methylism, with its accompanying cyanosis, dyspnea, coma, dilated pupils, etc., the nature of the affection is in any way suggested is contradicted by the early experiences in the recent Berlin episode. In recovered cases there are apparently no sequelæ—when blindness has not occurred—to cause suspicion as to the true nature of the antecedent illness. At a recent meeting of the Leipzig Medical Society (*Deutsche medizinische Wochenschrift*, February 8), Marchand, the well known pathologist, reports three autopsies on victims of acute methylism. There was either an absence of pathological finds or these were at best equivocal. One victim had died comatose, with cyanosis, dyspnea, and absence of radial pulse. He showed no pathological finds whatever. One test of the stomach contents for methyl alcohol resulted positively. Another subject died with delirium, fever, wretched pulse, and badly reacting pupils. There was found hyperemia of the meninges and most of the viscera, but the intestine and kidneys showed no lesions. There was methyl alcohol in the stomach contents and formic acid and acetone in the urine. The viscera, all had a strong acetone-like odor. In a third case tests of the stomach contents for methyl alcohol gave conflicting results, but there was formic acid in the urine and the viscera smelled strongly of acetone. It is evident that some difficulty may be experienced in proving death from methylism if cases of forensic import occur.

News of the Week.

Vital Statistics of New York City for February.—The number of deaths recorded during February, 1912, was 6,546, giving a death rate of 15.94 per 1,000, compared with 6,470 deaths and a rate of 16.94 per 1,000 in the corresponding month of 1911, a decrease of exactly one point per thousand in the death rate, corresponding to a lessened mortality of

431 persons during the month. The causes showing a decreased mortality were as follows: Scarlet fever, 19; whooping-cough, 19; influenza, 50; cerebrospinal meningitis, 13; acute bronchitis, 17; chronic bronchitis, 23; bronchopneumonia, 25; other respiratory diseases, 29; diarrheal diseases under five years of age, 79, and cirrhosis of the liver, 37. The causes showing increased mortality were as follows: Typhoid fever, 12; measles, 10; tuberculosis of the lungs, 55; cancer, 47; apoplexy, 32; organic heart diseases, 140; lobar pneumonia, 41; Bright's disease and nephritis, 11; old age, 11; accidental deaths, 10; homicides, 23, and suicides, 6. The decreased mortality from diarrheal diseases under five years of age is considerable and may be indicative of the effect of the increase in the number of infants' milk stations established, and the accompanying dissemination of information among the mothers who obtain milk from these depots. There were 95 deaths of non-residents recorded in the city during the month, which if deducted from the total number of deaths would give a death rate of 15.70 per 1,000 for the entire city. There were 11,093 births recorded during the month, an increase of 287 over the corresponding month of last year.

Bacteriologist (Male) Wanted in the Philippine Service.—The United States Civil Service Commission announces an examination to secure eligibles from which to make certification to fill a vacancy in the position of research bacteriologist in the biological laboratory of the Bureau of Science, Manila, Philippine Islands, at a salary of $2,500 a year, and vacancies requiring similar qualifications as they may occur in the Philippine Service, unless it is found to be in the interest of the service to fill the vacancy by reinstatement, transfer, or promotion. It will not be necessary for applicants to appear at any place for examination. Their eligibility will be determined upon the evidence furnished in connection with application and examination Form B. I. A. 2, concerning their training and the work which they have accomplished. Applicants may, if they desire, submit with their applications copies of theses or publications which have been prepared by them. This position is for a research bacteriologist with clinical experience, and applicants must be graduates in medicine; in addition they must show that they have specialized extensively in bacteriology and are capable of doing original research work. The ordinary bacteriological training incident to a medical course or a hospital interneship will not be considered in this connection. All statements relating to training, experience, and fitness are subject to verification. Applicants must be willing to enter into a contract requiring at least two years' residence in the Philippine Islands. The work comprises investigations in tropical medicine in conjunction with the chief of the biological laboratory, who is also professor of tropical medicine in the College of Medicine and Surgery. The clinical material of the Philippine General Hospital and the hospital of the government prison will be available for study in connection with bacteriological investigation. It is stated by the Bureau of Science that opportunities exist for promotion to higher places as vacancies occur, and at present there are six positions in this laboratory above the one in question, at salaries ranging from $2,500 to $5,000 a year. The library of the Bureau of Science and the equipment are of the very best and strictly modern, so that this position offers a unique opportunity for a young man who is ambitious and who desires to make a name in research work in this specialty. Age limit, eighteen to forty years on the date of the examination. Applicants should at once apply for Form B. I. A. 2 to the United States Civil Service Commission, Washington, D. C., to the secretary of the board of examiners, post office, Boston, Mass., Philadelphia, Pa., Atlanta, Ga., Cincinnati, Ohio, Chicago, Ill., St. Paul, Minn., Seattle, Wash., San Francisco, Cal.; customhouse, New York, N. Y., New Orleans, La., Honolulu, Hawaii; old customhouse, St. Louis, Mo.; or to the chairman of the Porto Rican Civil Service Commission, San Juan, P. R. No application will be accepted unless properly executed, including the medical certificate, and filed with the Commission at Washington prior to the hour of closing business on April 6, 1912.

The Hot Springs of Arkansas.—By act of April 20, 1832, Congress provided that four sections of land in the territory of Arkansas, including the Hot Springs, a total of 2,560 acres, should be reserved from sale or entry in order that they might be preserved in perpetuity for the benefit of the sick. When the State of Arkansas was created the Federal Government still retained the ownership of the four sections, but did not reserve the jurisdiction. By later acts the size of the reservation was reduced to 911 acres, the present area. All of the springs are on the Government reservation, but there has grown up around them the city of Hot Springs, over which the Government has no jurisdiction or control. The result was that the city of Hot Springs became what is known as a "wide-open" town, much to the detriment of the place as a health resort. The National Government has, however, succeeded in doing away with most of the abuses and has also appointed a medical director to have full supervision of sanitation, hygiene, and all that pertains to the bathing of patients. A recently issued report of the medical director, Dr. H. M. Hallock, is the first official publication by the Department of the Interior dealing directly with the medical problems involved. Under the supervision of the medical director considerable progress has been made in bettering those conditions that are of especial medical interest. Two new sanitary bathhouses have been fully equipped and provided with a complete blast system of ventilation, and a third has been entirely remodeled, enlarged, ventilated, and made sanitary in every respect.

Faculty Changes at Tufts.—Announcement is made of the appointment of Dr. William Merritt Conant to the chair of clinical surgery at Tufts Medical School to succeed Dr. David D. Scannell, resigned. Dr. William Allen Brooks, Jr., is appointed assistant professor of clinical surgery. Dr. Frederick M. Briggs has been made professor of surgery.

The Massachusetts State Board of Registration was subjected to sharp criticism by the committee on public health of the State Legislature on March 12. Charges were made that the examination questions are kept secret so that they need not be varied from one examination to the other, that applicants are examined on subjects not required by statute, that the graduates of one medical school are discriminated against in the examinations, and that in at least one instance a candidate who had been rejected was subsequently granted a license upon threatening to bring suit against the board.

Suit by a Nurse for Reinstatement.—A jury before Supreme Court Justice Newburger recently brought in a verdict for the defendant in a suit by a woman for many years supervising nurse at Harlem Hospital, for a writ of mandamus directing the board of trustees of Bellevue and Allied Hospitals to reinstate her. The jury found that the nurse's place had been abolished for the sake of economy and that her removal was in good faith.

Dr. Harvey W. Wiley, Chief of the Bureau of Chemistry of the Department of Agriculture, resigned on March 15, his resignation being accepted with expressions of regret from both President Taft and Secretary Wilson. Dr. H. R. Bigelow, Dr. Wiley's former assistant, is temporarily in charge of the bureau, and is spoken of as his probable successor. Others who have been mentioned as possible appointees to the position of chief chemist are Dr. William J. Gies, professor of chemistry at Columbia University, and Dr. Lucius P. Brown of Tennessee, who was president of the National Pure Food Congress last year. Dr. Wiley's resignation was purely of his own volition, and it is denied that any pressure was put upon him to leave the department. It is announced that he will be contributing editor to *Good Housekeeping* magazine.

A Bacteriological Quarantine Board.—Announcement is made by the Health Officer of the Port that he has appointed four pathologists to take charge of the bacteriological laboratory at Quarantine and to be responsible for the diagnosis of suspects in case of a threatened invasion by cholera or other infectious disease. The new board consists of Drs. F. C. Wood and John Larkin of the College of Physicians and Surgeons, Dr. James Ewing of Cornell Medical School, and Dr. Joshua Van Cott of the Long Island College Hospital.

Charged with Not Reporting Meningitis.—The house surgeon of the Charity Hospital, New Orleans, has been charged by the president of the City Board of Health with failure to report fifteen cases of cerebrospinal meningitis. The accused official denies that he has failed to report any cases of communicable disease in the hospital and says there are no cases there of meningitis.

Neosalvarsan is the name given by Ehrlich to a modification of 606 which forms a neutral solution in distilled water without the use of any other solvent. The Berlin correspondent of the *New York Times* says that the modified 606 can be given in larger doses than the original without any untoward effects and that the technique of its administration is reduced to the simplest form. Dr. Schreiber of Magdeburg is experimenting with the modified drug and will soon publish his report.

Adrenalin in Cholera.—A despatch to *The Sun* from Tunis states that Dr. Naame, a French physician of that place, claims that the intravenous injection of adrenalin is positively curative in cholera. He says that he has employed the remedy in twenty cases of cholera, recovery being obtained in every instance.

Vivisection Necessary.—The *New York Times* states that the report of the British Royal Commission on Vivisection as to experiments on animals which have been adequately safeguarded in a legal manner is to the effect that they are morally justifiable and should not be prohibited. The investigation of the commission has extended over a period of six years.

Medical Society of the State of New York.—The 106th annual meeting of the Medical Society of the State of New York will be held at Albany on April 16, 17, and 18, 1912. Not only the members of the Medical Society of the State of New York, but also all physicians in good standing, will be welcome. The meetings open to the public are the address of Dr. Wiley, Tuesday noon; the evening addresses on "Prevention of Blindness," "Prevention of Deafness," "Prevention of Insanity," "Prevention of Tuberculosis," and the address of Dr. Cannon on "The Benefits of Vivisection to Mankind." Also, all the meetings in the Section on Public Health will be open to the public. The other meetings are strictly medical and open only to the profession, but medical guests are welcome.

The Spalding County, Ga., Medical Society, at its meeting on March 7, elected the following officers: *President*, Dr. E. R. Anthony; *Vice-President*, Dr. J. S. Wells; *Secretary*, Dr. J. M. Thomas; *Censor*, Dr. T. J. Phillips.

Canadian Military Medical Officers.—The fifth annual conference of the Association of Medical Officers of the militia of Canada met in Ottawa on February 28 and 29. Addresses were made by Colonel Samuel Hughes, Minister of Militia; Sir James Grant of Ottawa, Major J. T. Clark of Halifax, Dental-Surgeon Lanthier of Quebec, and a number of papers on military medical topics were read and discussed.

A Discussion on Mental Diseases.—There is to be held in Chicago, April 17, 18, and 19, 1912, a meeting under the auspices of the West Side Branch of the Chicago Medical Society and the Chicago Medical Society for the purpose of discussing mental diseases in their various phases. Alienists and neurologists from different States have been invited to participate in this meeting. The object of the meeting is for scientific purposes for those engaged in this line of work, educational to the general practitioner, and educational to the public.

American Urological Association.—At a meeting of the New York Society of the American Urological Association held at the Academy of Medicine, March 6, 1912, the following officers for the year 1912 were elected: *President*, Walter Brooks Brouner; *Vice-President*, Benjamin S. Barringer; *Secretary*, Clarence R. O'Crowley; *Treasurer*, Julius J. Valentine. The American Urological Association will hold its annual meeting at the Hotel Astor, April 2, 3, and 4, being the guests of the New York Society. The morning sessions will be devoted to visiting the various genito-urinary clinics here. The afternoon sessions will be devoted to the reading and discussion of scientific papers.

The Late Dr. Weber.—At a stated meeting of the Medical Board of St. Mark's Hospital the following resolutions were unanimously adopted: *Whereas:* Dr. Leonard Weber, the consulting physician of our Medical Board, has departed this life Therefore, be it resolved: That the medical profession loses in him one of its foremost members and New York City one of its most brilliant men. Further resolved: That we deplore in his demise the loss of a most faithful co-worker, and St. Mark's Hospital the absence of a most efficient benefactor. Further resolved: That these resolutions be spread upon the minutes of our board, and a copy thereof be sent to his bereaved widow, and the same be published in the MEDICAL RECORD and the *New York Medical Journal*. Signed, C. A. Von Ramdohr, M.D., Chairman; Benjamin T. Tilton, M.D.; Ignatz Morvay Rottenberg, M.D., Committee.

Obituary Notes.—Dr. FREDERICK H. COLTON of

Brooklyn, N. Y., died on March 10 at the age of 73 years. He was born in Long Meadow, Mass., was graduated in arts from Yale College in 1860 and in medicine from the Long Island College Hospital in 1864. While a student he served a year during the Civil War in the medical corps of the U. S. Army. He was visiting physician at the Long Island College Hospital, St. John's Hospital, and the Brooklyn Home for Aged Men and Cripples. He was president of the board of directors of the Eye and Ear Hospital and was a member of the Kings County Medical Society, the Medical Society of the State of New York, the Practitioners' Club, and the Associated Physicians of Long Island.

Dr. THOMAS A. SCHERER died at Catasaqua, Pa., on March 9, at the age of fifty-eight years. He was graduated from Jefferson Medical College in the class of 1883.

Dr. ALVERD E. WINCHELL, who was the oldest member of the Connecticut Medical Society, and a prominent physician in New Haven, died March 7, of pneumonia, at the age of eighty-one years. He was a graduate of the College of Physicians and Surgeons, New York, in the class of 1865.

Dr. ALEXANDER HADDON of New York City died on March 16, of disease of the heart, at the age of 79 years. He was born in Orange County, N. Y., and was graduated from the College of Physicians and Surgeons (Columbia University) in 1859. He was one of the organizers of the Northeastern Dispensary, and was also for thirteen years on the attending staff of the Presbyterian Hospital.

Dr. MARY FRANCIS BUTTERWORTH of Revere, Mass., died on March 13 at the age of 66 years. She was born in Beverly, Mass. On the death of her husband, Chief Engineer James Butterworth, U.S.N., in 1891, she began the study of medicine and was graduated from the Tufts Medical School in 1895.

Dr. JOHN MILLER KENNEDY of this city died March 12, at the age of 49 years. He was a graduate of the College of Physicians and Surgeons (Columbia University) in 1887, and was a member of the Society of Alumni of City Hospital, and of the West End Medical Society.

Dr. CARLOS P. TUCKER, a graduate of the College of Physicians and Surgeons in the class of 1849 and for fifty-seven years a practicing physician in this city, died on March 10 at his home in Mount Vernon. He was born 90 years ago at Exeter, N. Y. Dr. Tucker was attending surgeon at Trinity Infirmary for many years and he was one of the earliest members of the Academy of Medicine.

Dr. H. HAMILTON RICKABY died at his home in this city on March 10, in his seventy-first year. He had practiced medicine in New York for forty-five years, after being graduated in medicine from the New York University in 1867. He was a member of the staffs of the Metropolitan and Hahnemann Hospitals and for several years was superintendent of the West Homeopathic Dispensary.

Dr. WILLIAM SPRENGER of New Haven, Conn., died March 13, at the age of 64 years. He was born in Switzerland, studied medicine in Germany, and served as surgeon during the Franco-Prussian war, being decorated with the Maltese Cross for his services. Later he came to America, and obtained a medical degree from the University of Vermont in 1891. He was an *x*-ray expert, and was at one time instructor in the use of the Roentgen ray at the Yale Medical School. He had had a cancer of the hand resulting from an *x*-ray burn.

Correspondence.

THE MODIFICATION OF COW'S MILK.

TO THE EDITOR OF THE MEDICAL RECORD:

SIR:—The following formulæ for modifying cow's milk have been found to be efficacious and easier to remember than the formulæ given in the text-books. In comparing the composition of human milk and cow's milk, the following differences are to be noted:

Human milk: Protein, 1.5 per cent., fat 4 per cent., sugar 7 per cent. Whole cow's milk: Protein 4 per cent., fat 4 per cent., sugar 4 per cent. Top 4 ounces of 1-quart bottle of milk after standing for six hours: Protein 4 per cent., fat 20 per cent., sugar 4 per cent.

If it is desired to make a mixture consisting of a total of 20 ounces, the following calculation may be performed:

1. What percentages of fat, proteins and carbohydrates do we need for the 20 ounces of the mixture? The answer is: $1.5 \times 20 = 30$ per cent. protein; $4 \times 20 = 80$ per cent. fat; $7 \times 20 = 140$ per cent. carbohydrate.

2. How many ounces of the whole milk are needed to furnish the required percentage of protein? The answer is: $30 \div 4 = 7\frac{1}{2}$ ounces.

3. What percentages of fat and carbohydrate are contained in the $7\frac{1}{2}$ ounces? The answer is: $4 \times 7\frac{1}{2} = 30$ per cent. of fat; and $4 \times 7\frac{1}{2} = 30$ per cent. of carbohydrate.

4. What percentages of fat and carbohydrate are missing in the mixture? Answer: $80 - 30 = 50$ per cent. of fat; $120 - 30 = 90$ per cent. of carbohydrate.

5. How much cream should one take of the upper 4 ounces in order to obtain the necessary 50 per cent. of fat? Answer: $50 \div 20 = 2.5$ ounces.

6. How much carbohydrate do we add to the mixture by using $2\frac{1}{2}$ ounces of cream? Answer: $4 \times 2\frac{1}{2} = 10$ per cent.

7. How much more carbohydrate do we need in our 20-ounce mixture? Answer: $90 - 10 = 80$ per cent.

8. How much sugar do we have to add in order to get the full percentage of carbohydrate? Answer: 1 ounce = 480 grains of pure sugar = 100 per cent.; $X = 80$ per cent.; or $480 \div 100 = X : 80 = 384$ grains.

9. How much milk and cream are needed for the 20-ounce mixture? Answer: $7\frac{1}{2} + 2\frac{1}{2} = 10$ ounces.

10. How much water do we have to use for this 20-ounce mixture? Answer: $20 - 10 = 10$ ounces.

The completed formula will be as follows: Whole milk, $7\frac{1}{2}$ ounces; upper 4 ounces of cream, $2\frac{1}{2}$ ounces; sugar, $6\frac{1}{2}$ drams, and water sufficient to make 20 ounces.

M. A. HELFGOTT, SR., M.M.C.
1323 HOLLINS ST., BALTIMORE, MD.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

TROPICAL SCHOOL—CANCER RESEARCH—EXOPHTHALMIC GOITER—INSURANCE—OBITUARY.

LONDON, March 1, 1912.

ON Wednesday the Lord Mayor, Sir T. Crosby, M.D., presided at the Mansion House over a meeting of which the object was to raise £10,000 in aid of the London School of Tropical Medicine. The Secretary of State for the Colonies, Mr. L. Harcourt, made an earnest appeal, read a letter he had

received in favor of it from his great predecessor, Mr. Joseph Chamberlain, and gave some details as to the progress made and the prospects open. He was informed that 1,300 students had been trained, nearly 500 of whom had passed into the service of the Dominions and Crown Colonies, and many colonial officials had profited by a stay in the hospital, which was placed in proximity to the wharves where ships from all ports brought victims of tropical diseases. Sir Patrick Manson, to whose foresight the school owed its existence and who had been all along its senior physician and teacher, read the official report. The contributions announced amounted to £2,293, to which is to be added £250 given by a gentleman present after the close of the proceedings.

At the annual meeting of the Cancer Hospital on Wednesday it was reported that the feature of the year's work was the completion of its Research Institute. In the electric and radiotherapeutic department, for which a new building would be opened about May next, a large supply of radium was secured. Dr. Robert Knox, head of this department, said that up to the present he saw no indication that it would take the place of operative measures. X-rays had been beneficial in a large percentage of cases by relieving pain. The chairman said that the new Research Institute of this hospital opened some months ago by the Duke of Connaught, was in construction and equipment a model of its kind—the most perfect for its purpose to be found anywhere.

I gave you last week a pretty full account of Dr. T. P. Dunhill's great experience and success in the surgical treatment of exophthalmic goiter. But there is more to be said, and the meeting of the three sections of the R. S. M. has had to be adjourned twice to afford an opportunity of full discussion, the result of which will, I think, be to show that the very pessimistic prognosis that long prevailed has been for some time undermined by those who have had much experience in the disease. Writers and editors of manuals will have to modify many of their statements. Side by side with Dr. Dunlop's paper the meeting had before it a contribution from Dr. George Murray, the professor of medicine at Victoria University and physician to the Manchester Infirmary, who had been invited to state the general principles of treatment. Admitting thyroid autointoxication as now generally accepted as the cause of the symptoms, he held the treatment was comparable to that of other toxemias due to microbic infection. But we know that some cases spontaneously recover—this in his experience might occur at any time from nine months to seven years. In some cases a degree of tolerance might be established. Atrophy of the redundant epithelium seemed to occur and he had seen this go too far in a case in which the goiter symptoms gave place to those of myxedema.

Rest, bodily and mental, diminished the activity of the thyroid. Diet had some effect. Excess of proteids should be avoided. The milk of goats and other animals after removal of their thyroids had been tried, so had their serum and even dried blood. Arsenic and belladonna seemed to depress the activity; iodine had the opposite effect. Cytolytic serum was not specific and was apt to produce degeneration of other organs. X-rays tried in one case failed, but on operation he found some changes suggesting that a longer course might have succeeded. Some adhesions to trachea might also have been due to the rays. A mild faradic current two or three hours a day had seemed beneficial and possibly reduced activity. Of 300 cases he had seen (276 women and 24 men) 10 were operated on, 9 by partial thyroidectomy, and 1 by ligature of both superior thyroid arteries. The first 3 cases died almost immediately; 1 man 4½ years ago after 9 years was ligatured and now is generally improved and can cycle; another partially thyroidectomized in May, 1911, was cured by September. A woman anxious for operation on account of pain, had 1 lobe removed in 1907 and is now well. Another in 1910 has still some symptoms, but is greatly improved, pulse 76 instead of 130. In 6 of his 10 cases 4 were operated on for pain or dyspnea. Of the 7 survivors 2 are cured, 4 are improved, and 1 has just recovered from the operation. He would advise operation whenever there is distinct stridor from compression or persistent pain in the enlarged thyroid, but not in mild cases, nor in very severe ones with marked cardiac failure. In moderate cases if full medical treatment for 12 months proved useless he would recommend surgery. The grave dangers that formerly deterred have been remarkably reduced.

Sir V. Horsley did not adopt Dr. Dunhill's four classes, but thought three sufficient: (1) true exophthalmic goiter with watery secretion; (2) parenchymatous with exophthalmic symptoms; (3) very rare cases when the whole gland was diseased and he removed it all and grafted normal gland beneath the peritoneum. He agreed with Dr. Dunhill that the danger was practically nil, except in dernier ressort cases. He had given up ligature of arteries as less effective than excision. No medical treatment would cure in an adult but should be tried for at least three months before operation. Many cases got well spontaneously or under rest and faradism. He had only operated under general anesthesia.

Mr. Leedham-Green of Birmingham referred to the mortality of six German surgeons stated at the congress last year, which differed between 3 and 17.3 per cent. Comparison with average conservative treatment was not easy for want of full statistics, but many hundreds of published cases gave an average of 15 per cent. His own cases were 30 in number and 3 had died (1 from pneumonia, 1 heart failure, 1 weeks later from phthisis); of the others 2 had relapsed from hypertrophy of the other lobe. All the others were at work. His best results were when he removed most tissue. He used local anesthesia.

Mr. Lynn Thomas of Cardiff said most cases in Wales came from near the sea; none from the mountains to which he sent patients after operation. Emotional disturbance was an important factor in this disease and he had seen a case die from it, so an eye should be kept on patients after operation. Dr. Hale White had investigated many cases with the aid of an actuary and found the mortality of healthy persons at the same ages five against eight of goiter cases not operated on. Years must elapse before we can compute the expectancy of life of persons whose thyroids have been removed.

Dr. Hector Mackenzie wanted more detail of Dr. Dunlop's cases, but did not give much as to his own experience. He did not think the operation could ever be regarded as necessary.

Dr. Albert Kocher said that at Berne they had done 865 operations on 669 patients, of whom 130 suffered from simple hyperthyroidism and all but two were cured. (They died of postoperative

pneumonia.) For progressing Graves' disease 539 were operated on and the results of 300 collected so far, giving 160 or 45 per cent. radical cures. More than half of the 160 were very severe and of long duration and in some several operations, up to 5, were needed; 149 still had some symptoms, though they were much benefited; 5 per cent. had had recurrence but in milder form; 6 per cent. died from other diseases. He thought all might be cured if operated on soon after the outbreak of the disease. In four cases only was a general anesthetic used and that because of the patient's lack of self-control. His objection to it was the liability to vomiting after it and the difficulty of sparing the laryngeal nerve.

M. Wilfred Trotter thought it reasonable to run some risk to avoid years of a very miserable condition. From simple goiter he had not lost a case, but in exophthalmic cases the mortality was about 10 per cent., but he operated on very bad cases, as those most in need of relief, and in which the results were most brilliant. More than half his cases were severe. A reduction of mortality to 5 per cent. should be possible and then operation could be done on a large scale. He used atropine, morphine, and scopolamine followed by ether. The atropine restrained the excess of mucus and should be acting before the anesthetic was given. Fear caused excessive tachycardia when the pulse might be uncountable for hours. The anesthetic did not steady such a case and the least laryngeal spasm might be fatal. He had his patients anesthetized in bed in the ward. Speed in operating was less important than gentleness, for dragging on the nerve or injury to the tissue must by no means occur. Drainage might sometimes be necessary after ether, otherwise he did not use it.

Dr. D. Buxton made some remarks on anesthesia. Some patients were shown by Messrs. Paterson and Berry and the discussion again adjourned.

The Insurance Act seems to be giving trouble outside the profession. The commissioners have been sufficiently perturbed by the dissolution of a number of the smaller Friendly Societies to send out a letter urging them to refrain from doing so. They are also making, they say, every effort by lecturers and conferences to give information as to the working of the act and to its effect on the societies. It does not say much for the care with which an Act of Parliament has been drafted, that it should be necessary to engage a band of lecturers to explain it to those it most concerns. The rules of the Friendly Societies appear to be drawn up with more care.

The medical men of various societies and sick clubs whose contracts expire at midsummer are giving notices that the agreements will not be renewed on the same terms.

In the House of Commons last night inconvenient questions were asked about the patronage being bestowed under the act and the offices created and the salaries, but the Government replied by closing the subject.

Dr. Alfred Harry Young, late professor of anatomy and pro-vice-chancellor, Manchester University, died on the 23d ult., aged 60. He had been an examiner for Oxford, London, Liverpool, and Birmingham Universities as well as for the Royal Colleges. Was consulting surgeon to the Salford Royal Hospital, the Manchester Consumption Hospital, and various institutions, and ex-president of several medical societies. He went to Manchester in 1877 and retired in 1909 on account of ill health. He lectured at Owens College before its incorporation in Manchester University. In 1885 took the chair of pathology and was appointed Dean of the Medical School. The degree of LL.D. was conferred upon him. He wrote on embryology and other subjects in Cunningham's Text-book and edited "Studies in Anatomy from the Anatomical Department of Manchester University."

Sir Francis R. Cruise, M.D., LL.D., D.L., Physician to the King in Ireland, died on February 26. Born in 1834 he graduated in Dublin University—M.A. 1856 and M.D. 1858. In 1861 he was elected on the staff of the Mater Misericordiæ Hospital, which he served for many years. He was president of the Royal College of Physicians in Ireland from 1884 to 1886. In 1901 was appointed physician in ordinary to King Edward. A knighthood was conferred on him in 1896. In 1905 he received from the Pope the decoration of St. Gregory. Sir Francis was a lineal descendant of Sir Maurice Cruise, who settled in Ireland in the twelfth century and whose tomb, with the date of his death (1216), still exists near the ruins of Cruisetown Castle. Besides numerous contributions to medicine Sir Francis wrote the Life of Thomas à Kempis and a revised translation of the "Imitation of Christ," as well as various articles on the subject. He had made a profound study of everything relating to à Kempis, who he held to be the author of the "Imitation."

Another loss to the profession in Dublin is by the death of Dr. Henry Fitzgibbon, which occurred on February 23, in his 71st year. He graduated from Trinity College in 1866 and for a time engaged in general practice. But after a time was appointed surgeon to the City of Dublin Hospital, next to the Westmoreland Lock Hospital, and consultant to Mercer's Hospital. He held many other important posts in Dublin, including visitor in Lunacy, member of the Board of Superintendence of the Hospitals. He was president of the Royal College of Surgeons in 1888-9. He made many valuable contributions to the societies, to the *Medical Press and Circular*, and other journals.

Dr. J. Blake Maurice, J.P., died suddenly on February 14, aged 72. He qualified in 1861, took M.D., St. And. the next year, and the F.R.C.S. in 1864. He was a magistrate for Wiltshire and medical officer at several institutions in the country.

Dr. M. Ogilvy Ramsay, surgeon to the Cumberland Infirmary, died on February 15 after four days' illness. He was M.A., St. And., and M.D., Edin, 1895, as well as F.R.C.S. Ed. He had practised in Carlisle for some 20 years, where he was greatly esteemed and will be deeply regretted. He contributed "Reports on Influenza" to *St. Bartholomew's Hospital Reporter*, 1890, and "Tracheotomy in Diphtheria" to the same.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

OFFICERS OF THE ACADEMY OF MEDICINE FOR 1912—DISINFECTION OF THE HANDS BY ALCOHOL—SURGICAL MEASURES FOLLOWING THE ACCIDENTAL INGESTION OF CORROSIVE LIQUIDS—PROGNOSIS OF BRIGHT'S DISEASE BY THE AMOUNT OF UREA IN THE BLOOD—PROFESSOR LANNELONGUE.

PARIS, January 30, 1912.

THE Academy of Medicine installed its officers for 1912, with Gariel as president, with Chaveau unanimously elected vice-president, and with Blanchard

as secretary. The disinfection of the hands by alcohol was the subject of papers by Marquis and Savariaud. This measure has been made the subject of numerous works and a certain number of surgeons make constant use of this method of disinfection. Until lately it was thought that the disinfectant properties of alcohol were almost nil. Marquis thinks, on the contrary, that alcohol owes its antiseptic power to its penetration. By the use of a special procedure he shows that this impregnation reaches to the bases of the hair follicles. Alcoholization of the hands should last for four minutes at least, and be made with alcohol with a degree of concentration of 90 to 100 per cent. Hands disinfected thus remain sterile for from 15 to 30 minutes; this use of alcohol may be made without that of soap or previous washing. It presents considerable advantages in time of war, it affords a saving of time and labor, and permits us to solve economically the problem of disinfection of the hands.

Pierre Delbet thinks that when the hands are soiled with cultures of microbes with resistant spores we can never be sure of sterilization. Delbet made a series of experiments on this subject; after having touched cultures of microorganisms he dried his hands by placing them in a current of air from a ventilator. After complete desiccation he commenced to cleanse his hands by washing them with soap, then with alcohol and hydrogen dioxide, 12 volumes solution. When the hands were supposedly clean he introduced them into balloons filled with bouillon culture and moved them about for five minutes, all precautions being taken during these manipulations to prevent contamination from without. To appreciate approximately the number of microbes left on the hands the whole amount of bouillon was placed in 514 culture tubes; all these tubes were contaminated. Delbet says that his confidence in the possibility of asepsis of the hands has been so shaken by the results of these experiments that he no longer dares to operate without gloves.

A paper dealing with the surgical operative measures necessitated by the accidental ingestion of corrosive liquids was recently presented by Potherat and Mauclaire. As a result of the ingestion of corrosive liquids there occur ulcerative, inflammatory, cicatricial, retractile, and stenosing lesions in which two distinct phases may be distinguished: one primary, immediate, due to the ingested corrosive liquids; and a second due to the occurrence of pyloric stenosis by cicatricial retraction. In the case presented by Potherat it was remarkable to note that the caustic which had severely burned the stomach in the pyloric region had traversed the mouth, pharynx, esophagus, and cardia without burning them; the liquid seems not to have a corrosive action except after it has stagnated for a time.

Mauclaire had occasion to attempt an operation two hours and a half after the ingestion of hydrochloric acid, for the purpose of evacuating the stomach contents, to wash it out with an alkaline solution, and finally to suture the stomach if there was any perforation. Now in the course of the operation Mauclaire found that there was a perforation on the anterior wall of the size of a five centime piece. The peritoneal cavity already contained a sero-sanguinolent liquid. The peritoneum and the posterior cavity of the omentum were drained, the perforation in the stomach was sutured to the skin, lastly an injection of Vichy water was made into the stomach. In spite of his care the patient died some hours after the operation. Mauclaire thinks that in all such cases an immediate operation should be done, for to wait and attempt lavage of the stomach is to lose precious time and is often impossible, because of the spasm of the esophagus and cardia prevents catheterism in many cases.

At the Medical Society of the Hospitals Fernand Widal discussed the prognosis of Bright's disease from the dosage of urea in the blood. The amount of urea in the blood is of importance in giving a prognosis of Bright's disease. In the question so difficult to solve of the prognosis of renal insufficiency it is the amount of urea in the blood that furnishes the only exact element that we possess at the present time. The importance of the examination of nephritic blood from the point of view of its content in urea is of considerable practical worth.

In the normal condition the amount of urea varies between 0.15 and 0.50 per liter of blood serum; when the proportion of urea passes 0.50 there is retention. The organism cannot long tolerate doses higher than 4 grams per liter of blood. The symptoms which accompany retention of urea in the blood are loss of appetite, torpor, pruritis, and uremic retinitis. The interest in the examination for urea in nephritic blood is that it furnishes exactitude in the prognosis and thus allows us to judge accurately of the gravity of the situation which nothing in the general condition of the patient would show.

Professor Lannelongue, President of the Academy of Medicine of Paris, Member of the Institute, died at the age of 70 years. This eminent master had a peculiarly brilliant career. Especially known are his remarkable works on bone suppurations, from osteomyelitis to tuberculosis, and everyone knows the clarity with which he portrayed these conditions up to that time so confused. It was he who showed the tuberculous nature of cold abscesses, fungous arthritis, and numberless cases of arthritis in infancy, before him so confused, so clear since his discoveries. It is for this that the name of Lannelongue will live in the future as the name of a creator. The scientific work of Lannelongue is of great importance in extent and originality. Aside from numerous publications on tuberculosis he was the author of many other works on various subjects. To popularize the results of his experience Lannelongue held weekly clinics for fifteen years at the Hôpital Trousseau, which were much frequented. Aside from his eminent scientific position he had many friendships in the political world. He was the friend and confidant of Gambetta, whom he had the grief to see die because illustrious physicians refused his advice. This man of such large intelligence devoted the last years of his life to a voyage around the world, which he made the subject of a book full of youth and ringing with patriotism. Lannelongue was Senator, Commander of the Legion of Honor, and a high dignitary in many foreign orders. In the midst of all this distinction, of which he realized the ephemeral nature, he was wise enough to remain simple, exempt from pretension, and easy of access to the afflicted. The numerous important works of Lannelongue and of his distinguished pupils, inspired by his examples, will assure him an imperishable renown.

Observations on European and American Orthopedic Apparatus. W. H. Kraus.

The Treatment of Miscarriage.—E. B. Young and J. T. Williams studied the relative value of intrauterine douches, packing, and antiseptics in the treatment of miscarriage. On the basis of the results obtained in two thousand cases they conclude that salpingitis has been more common after intrauterine douches. Intrauterine douches of sterile water or salt solution have not given as good results as simply wiping the uterine cavity with sterile gauze. Antiseptic douches have given poorer results than simple sterile solutions. Swabbing the uterine cavity with tincture of iodine has given the best results. Packing the uterus to control hemorrhage does not greatly increase the liability to infection. For packing, gauze saturated with 50 per cent. alcohol in "clean," and plain sterile gauze in "infected" cases have given the most satisfactory results.

Methods of Favoring Proteid Digestion.—R. B. Hunt describes the various methods by means of which one may aid the child in the digestion of the excessive amount of insoluble casein contained in cow's milk. Boiling the milk prevents it from coagulating normally, if at all, with rennet. Cereal diluents have a twofold action: (1) they furnish a mechanical aid to the peristaltic action of the stomach in grinding the curd into more flocculent particles; (2) they have a colloidal action, the flocculi of precipitated casein being surrounded with a gelatinous envelope, and being prevented from coalescing into dense masses. Chemical agents aid proteid digestion either by the formation of soluble salts or by a retarding action on the enzyme rennin. The chief influence of lime water consists in its effect in retarding the clotting action of rennin. Bicarbonate of soda causes the liberation of carbon dioxide, which produces a more porous curd. If sodium citrate is used the sodium unites with the paracasein, forming sorium paracasein which is a fluid, while citric acid is liberated and unites with the calcium, forming the citrate of calcium which is absorbed. Predigestion of milk by means of pancreatin is a method that is used least of all methods. The use of whey eliminates the large mass of insoluble casein.

Amaurotic Family Idiocy.—R. M. Smith summarizes the symptoms of this disease as follows: (1) A progressive paralysis—flaccid or spastic in type—occurring in an infant previously normal and well developed; (2) blindness with typical changes in the fundi of the eyes; (3) mental deficiency going on to idiocy; (4) nystagmus, drooling, and gurgling in the throat; (5) occurrence in Hebrews, often in several members of the same family. The pathological findings of this disease are distinctive. The lesions are confined to the central nervous system. Every cell of the entire central gray matter, brain, cord, and spinal ganglia, is involved. The changes are degenerative in type and consist of a swelling of the cell protoplasm which by pressure causes a mechanical destruction of the cell fibrils. Ultimately the cell body is a mass of detritus. The axis cylinders are not involved in the process. The characteristic appearance in the fundi of the eyes is due to the degeneration of the ganglion cells of the retina and the nerve fibers of the optic nerves, which are, of course, really a part of the central nervous system. The cells are more numerous in the macula region than elsewhere, so that region appears white. The red spot is due to the contrast of the retinal vessels with the white surroundings.

Orthopedic Apparatus. W. H. Kraus advocates the standardization of certain common types of appliance. He would urge that, whenever it is practical, at least in the more complicated forms, the instrument maker be consulted in the presence of the patient and be allowed to take any measurements he desires. It is recognized that an ill-fitting apparatus may do harm, and rarely serves its purpose as a support. The brace should be so carefully worked out in detail that it may, as far as possible, adapt itself to give adequate support in whatever position or under whatever anatomical peculiarities it is called upon to serve. To attain this nicety of fit it is very important that the maker of the instrument should be allowed to take his own measurements of the patient. However, this should never be left entirely to the mechanician. There is at present no uniformity of type or style so that a hip brace, for example, can be fitted as the tailor fits an overcoat. The measuring, the fitting, and the working of the brace should all be carefully followed and observed by the physician in charge, who alone can fully appreciate the requirements.

The Moderately Contracted Pelvis.—E. McDonald states that any degree of pelvic contraction is only relative to the size of the fetus and a pelvis should be judged to be large or small as to whether or not it will admit the passage of the head. The ever present obstetric problem is whether a fetal head of unknown dimensions can be delivered through a pelvis whose measurements can be ascertained. For measuring the fetal head the author has devised the following method: An ordinary pelvimeter of simple construction is taken and two rings of adhesive plaster, about 1 cm. in width, are fastened to each tip. These rings are faced inside with adhesive plaster, back inward, and are made sufficiently large readily to admit the middle and index fingers. The knob-like tips of the pelvimeter should project about 1 cm. beyond the palpating fingers. The patient is laid on her back and the operator stands as if to palpate for the position of the head. An accurate diagnosis of the fetal position, not only in regard to the occiput, but also in regard to the flexion of the head is essential to success. The bladder must be empty. The occiput and sinciput are located; then the fingers are thrust into the rings and the knobs of the instrument approximated to these points as closely as possible. The weight of the hinge side of the pelvimeter is supported by the finger of an assistant, or may be held up by a string attached to the operator's arm or buttonhole. It is necessary that the hinge side should have free play of movement in order that one or other tip may be depressed, if occasion requires. The tips are held firmly against the cephalic poles and the scale is read. This gives the occipitofrontal diameter.

The Neglected "Cold."—J. B. Huber states that colds seem to be the exclusive privilege of civilization. The human race did not snuffle much until it began to build houses and to wear clothes. An essential element in the catching of colds has been the disturbance of equilibrium

in the body through constantly passing from the superheated home into low temperatures without the house. In some cases of catching cold there is a nervous element, but most cases are the result of bacterial infection. The catarrhal habit is favored by overeating, indigestion, and malnutrition.

Moral Problems of College Life.—S. Eggert states that from the mind of the young man at college should be eradicated the fallacious doctrine that sexual continence is incompatible with good health upon the part of men. The ethical and moral sense of the student should be appealed to and impressed along two lines: First, by emphasizing the importance and influence both physically and morally of one's present actions upon one's later life and especially with respect to one's future family relations, and secondly, by demonstrating the inevitable and positive influence for evil which is inflicted upon the participating woman.

The Bacteria of the Conjunctiva.—K. M. Lynch states that in order to determine the frequency and kinds of bacteria present in the conjunctival sac normally, and in both acute and chronic inflammatory conditions, a study of 200 spreads was made in the Philadelphia General Hospital in the summer of 1911. Spreads were made from the lower conjunctival surface, back near the fornix, with small cotton tipped wooden applicators, previously sterilized, and upon slides cleaned with alcohol. A summary of the study shows 57.6 per cent. of normal conjunctivæ to harbor the xerosis bacillus, 20 per cent. the pneumococcus, 3.8 per cent. the diplobacillus of Morax-Axenfeld, 3.8 per cent. staphylococci, 0.2 per cent. Friedländer's bacillus, 3 per cent. yeast fungi, and a few contain unrecognized bacteria, while in only 4 per cent. no bacteria can be found. In the acute cases it was demonstrated that practically always the conjunctival sac contained the xerosis bacillus immediately after a gonococcic infection, while the pneumococcus, pneumobacillus, and staphylococcus were each present in a few in pure culture. In the chronic cases the xerosis bacillus was demonstrated in nearly a hundred per cent., while mixed with it in a few cases were the diplobacillus of Morax-Axenfeld, the pneumobacillus, and the staphylococcus.

The Trace of Urinary Albumin.—B. G. R. Williams states that practically every urine contains a trace of serum albumin, which is revealed only when certain special methods are used. In order to obtain reliable deductions with regard to pathological albuminuria the Boston and the picric acid tests may be relied upon. The author recommends the following technique for the latter: Equal parts of the filtered urine and a filtered, concentrated, aqueous solution of pure picric acid are mixed in a test tube and set aside. After an interval of 15 to 40 minutes, the tube is examined beside a control with a sample known to be normal. If a sediment is present in the bottom of the tube, the test is probably positive. One should shake the tube well and hold it in the direct rays of the sun, comparing the control specimen. The milky appearance may be due to the serum albumin, but albumoses, peptones, and nucleoalbumins may likewise contribute. Then the sample should be heated. If the contents "clear," no true serum albumin is present. If the patient has been taking santal oil or copaiba, one should add an excess, twice the volume, of ether, shaking well to dissolve the resinous acids.

Spinal Decompression.—P. Bailey and C. A. Elsberg conclude that the free removal of spinous processes and lamina with the opening of the dura may have a profound effect on the spinal cord in certain pathological conditions. There are a number of intradural conditions which present symptoms as yet indistinguishable from those of spinal tumor. Even in the absence of increased intradural pressure or a discoverable lesion the operation of laminectomy and incision of the dura may be of great benefit. For these reasons and on account of its relative safety in experienced hands exploratory operations should be done more often.

Peritoneal Drainage.—W. Coughlin concludes from his experiments that the pelvic cavity could not be completely drained of water by raising the supine body even to 90 deg. "bolt upright." The pelvic cavity could be completely emptied of water by turning the horizontally placed body just more than midway between pronation and supination. Water found its way from the left loin to an exit just below and internal to the right anterior superior iliac spine with the body raised to 45 deg. in the right lateral position. With a distended condition of the intestines, although water gravitated less readily, practically the same results were obtained. Although water found its way from the left loin, it did not so easily find its way from the right loin to an exit just below and internal to the left anterior superior iliac spine; no matter how high the left laterally lying body was raised a quantity remained in the right loin.

Syphilis of the Liver.—V. L. Schrager notes that clinical statistics underestimate the frequency of syphilis of the liver. The Wassermann reaction reveals a greater number of cases. The symptom-complex of syphilis of the liver is not pathognomonic, as it simulates almost every hepatic disease; occasionally it simulates fabrile diseases. Whenever the diagnosis is uncertain, resort should be had to the therapeutic test as well as to the Wassermann reaction. Mixed treatment has a striking effect on lues of the liver frequently, regardless of the time it has existed.

Muscular Development.—H. M. Friedman states that it might be well to note that, aside from the ability of a well-developed muscular system to endure the physical hardships of life, a good musculature is necessary in order to have a healthy body; that muscular development is influenced by climatic, dietetic, and hygienic conditions; that frequent crossing between widely different races seems to lower the standard of physical development, as well as to a too close in-breeding; that, while civilization tends to a physical deterioration in general, much can be done to check this tendency through intelligent, systematic physical education, begun in childhood and continued throughout life.

The Occluded "S."—E. W. Scripture states that one of the most frequent defects in speech of the illiterate or the defective is the occluded "s." In making the normal "s" the tongue is pressed against the hard palate rather tightly, but a narrow groove is left in the middle so that a jet of air passes through, and it is this that produces the distinctive sound of "s." A child with the occluded "s" an-

parently uses "t" and "d" instead of "s" and "z," saying "tun," "toap," and "toup" instead of "sun," "soap," and "soup," and "Liddy" instead of "Lizzy." The occluded "s" may be defined as an "s" made with excessive tongue pressure closing up the narrow channel. Treatment by having the child imitate the "s" of normal speech usually aggravates the defect, as the child is already making too much effort with his tongue. One rarely succeeds in teaching him to relax the tongue directly. The treatment the author has used is to place a small stick probe over the middle of the tongue while the patient is saying "s." This makes a groove through which the air escapes with a hissing sound and makes it impossible to produce the "t" sound. After repeated trials the child learns to recognize the "s" and learns how to make it without the use of the stick.

Two Cases of Pneumonia Treated with Pneumococcus Vaccine. G. P. Jones.

Glycosuria.—A. E. Garrod states that transient glycosuria may result from widely different causes, the removal of which will restore the sugar tolerance. But in the majority of instances the impression is justified that diabetes once established is a permanent condition. There are racial and hereditary tendencies that favor an instability of the carbohydrate metabolism. Various organs of the body share in the causation of glycosuria. The author advances the following hypothesis: One may conceive of a group of enzymes carrying on the actual work of the metabolism of carbohydrates, as of other branches of metabolism. One may picture to oneself the glands of internal secretion as directing, controlling, and supervising the work of the enzyme laborers, now restraining their activity, and now stimulating them to increased exertions. Of the several glands concerned in this work, among which the pancreas stands preeminent, one may conceive of some as helping and some as hindering the actions of others, so that, if the influence of one of them be withdrawn, or be too powerfully exerted, the balance normally maintained is overthrown and disorder results. Lastly, one may picture these overseer glands as themselves controlled by a still higher authority resident in the nervous system, for the influence of the nervous system upon the glands of internal secretion hardly admits of doubt. The author discusses the relation between glycosuria and of the nervous system, diseases of the pancreas, liver, and intestines, and febrile disorders.

Significance of Symptoms in Duodenal Ulcer.—G. Mansell Moullin states that there may be an ulcer in the duodenum without symptoms of any kind (in many instances in which an ulcer has been found post mortem its existence had never been suspected during life); that the characteristic symptoms may be present without even so much as a white patch on the serous coat; that fairly deep ulceration may occur in the mucous membrane without visible change on the serous surface, post mortem at any rate; that a great deal may happen upon the serous surface in the way of thickening and adhesion without anything to correspond beneath; and that the presence of a trivial scar, far too small and too superficial to cause stenosis or obstruction, is not enough to account for the symptoms assigned to duodenal ulcer; and still less for their recurrence after perhaps years of freedom. The most characteristic symptom of duodenal ulcer is the pain. But hunger pain may and does occur in its most typical form in many other disorders besides duodenal ulcer, as in chronic ulcer on the lesser curvature of the stomach at the cardiac end, in gallstones, chronic inflammation of the appendix, and other abdominal troubles. The immediate cause of the pain in duodenal ulcer is not the irritation of the ulcer by the acid chyme passing over it, but is the violent muscular contraction of the muscular coat at or near the pylorus, which contraction is set up by the food leaving the stomach. As regards the significance of hemorrhage in duodenal ulcer it is stated that this symptom is of very frequent occurrence, much more frequent than is usually believed, but unless the hemorrhage is profuse it is no proof of the presence of an ulcer. Melena, where all the other symptoms point to the presence of an ulcer in the duodenum, may be regarded as confirmatory evidence; if it is in large amount, as strong confirmatory evidence; but there can be no question that ulceration of the duodenum may and does occur without melena, and that conversely small hemorrhages from the duodenum are equally common without ulcer. Though hyperchlorhydria is present in about 60 per cent. of cases diagnosed as duodenal ulcer, and though when present it may help in the actual production of the ulcer, its presence even in an exaggerated form is not evidence of the existence of an ulcer. The author asks: What is the real significance of these symptoms? What is the condition of the stomach and duodenum that underlies them all? And why do hunger pain, pyloric spasm, occult hemorrhages, gastrostaxis, and hyperchlorhydria occur in this association? The author is convinced that the solution is to be found in the intensely hyperemic and hyperesthetic state of the mucous membrane present in these cases.

Treatment of Cystitis.—D. Newman states that in mild *Bacillus coli* infection of the bladder internal medication is designed to lessen the irritability of the vesical mucous membrane, to hinder the propagation of the infective organisms, and to clear them out of the bladder. The administration of urinary antiseptics by the mouth and local applications to the bladder are not suitable during the acute stage, but they are indicated as the inflammation subsides. Irrigations with a 1 per cent. solution of boric acid are useful. The treatment of the severer forms of acute cystitis due to the pneumococcus, streptococcus, gonococcus or tubercle bacillus is constitutional and local The patient must remain in bed and the symptoms may be relieved by warm baths and sitz baths with aromatic herbs, or hot moist compresses may be kept on the abdomen. Diet should be plain and the quantity limited, and bland fluids should be given in considerable quantity. The drugs given must depend upon the reaction of the urine, but in all cases phenacetin and extract of hyoscyamus—for an adult 5 grains of each three times daily—should be taken. Opium should be avoided, but morphine may be given hypodermically if demanded on account of the pain. Vaccines are of special value in these cases.

Pruritus Vulvæ; Its Etiology and Treatment. R. A. Gibbons.
Retroversion of the Uterus. W. J. Gow.
Four Successful Cases of Cesarean Section. C. Y. Pearson.
The Diagnosis of Ectopic Gestation. R. Davies-Colley.
Albuminuria in Pregnancy. H. M. Raven.
Chickenpox During the Puerperium. B. Myers.

Pruritus Vulvæ.—R. A. Gibbons states that this condition may be symptomatic or essential. In the latter case it is a pure neurosis, which, however, is extremely rare. Most of the cases of true pruritus are in women who are passing through or who have passed through the climacteric period. Some cases of pruritus start from a

slight abrasion due to mechanical injury. A common association is with diabetes. Some observers attribute the pruritus in this instance to the local irritation by the sugar; others to some hematogenous cause analogous to that which causes the pruritus of jaundice, while others attribute the irritation to some constituent in the urine besides sugar. Local causes of pruritus are the pediculi and ascarides, the thrush fungus and the gonococcus. Other causes are lack of cleanliness, eczema, the presence of a pessary, masturbation, small varicose veins, and small ulcerations about the hymen. Kraurosis vulvæ is an important cause of pruritus. It has been described as an atrophic retraction affecting the vaginal orifice, the labia minora, the frenum and prepuce of the clitoris, and the inner surface of the labia majora. This retraction is accompanied by necrosis of the epidermis and by hyperplasia of the connective tissue, causing retraction and shrinking of the genital organs. The treatment of pruritus vulvæ is considered under three heads: internal remedies, external remedies, and operation. Internal measures include regulation of the diet, and the administration of bromides and similarly acting drugs. External remedies include the use of antipruritic lotions or ointments and soothing sitz baths such as the bran bath. A 5 per cent. solution of cocaine is often of great service. Liquor potassæ and solutions of corrosive sublimate and lead subacetate are frequently effective. Menthol in solutions of 5 to 20 grains to the ounce rarely fails to afford relief. Nitrate of silver applied in a strength up to 40 grains to the ounce is also of value, particularly in cases that have lasted for some time. The operative measures that have been recommended are the application of some form of cautery, the excision of the affected parts, and the division of nerves.

Diagnosis of Ectopic Gestation.—R. Davies-Colley states that a salpingitis should be suspected in the presence of a history of previous similar attacks or of a recent source of infection, hemorrhage profuse but not persistent, considerable pyrexia, a tumor, irregular, central, and very tender, and a rapid resolution. Hematocele may be diagnosed where there is no history of previous attacks and no recent source of infection; where the hemorrhage is slight in amount but persistent; when pyrexia is slight; when there is a unilateral and not very tender tumor; when there is very slow resolution, and when there are signs of pregnancy in the breast, etc.

Chickenpox During the Puerperium.—B. Myers reports a case of chickenpox complicating the puerperium, the peculiarities of which, as far as the mother was concerned, were the predilection of the pocks for the labia majora and breasts, parts which were, one may presume, receiving a more generous blood supply due to her recent pregnancy than would otherwise obtain. The appearance of the first spot on the buttock was unusual. This spot, although at first unlike chickenpox, subsequently went through the usual changes in a typical manner.

Berliner klinische Wochenschrift.

February 26, 1912.

Ozena and Diphtheria.—Neufeld refers first to the persistent obscurity concerning the nature of ozena which obtains in nearly all its aspects. Among the bacteria accused of causing the affection is one which is indistinguishable from the Klebs-Loeffler bacillus, which fact suggests naturally that subjects with ozena and perhaps with ordinary atrophic rhinitis may be diphtheria carriers. In most of the cases in which this bacillus was found in almost pure culture there was none of the odor of ozena. In some of the cases the bacilli were found to be virulent. In the series of cases in which this research was conducted, diphtheria had first been suggested by the clinical presence of so-called chronic pharyngeal diphtheroid, developing in pharynges which were the seat or ordinary pharyngitis sicca. In but one of six cases studied was there a history of ordinary diphtheria, and in but one case was Abel's ozena bacillus present. The conclusion reached by Neisser, who made this research, was merely that ozena may play a not unessential rôle in the spread of diphtheria. This theory, however, never made any headway among practical rhinologists, while Behring seems more or less sceptical concerning it. There is no question that a bacillus resembling Klebs-Loeffler's is frequently present in ozena. It is highly important that its identity with the latter be either proved or disproved once for all. The author has, therefore, studied fourteen cases of genuine ozena and seven cases of atrophic rhinitis with this end in view. The research was necessarily highly technical in character and the conclusion reached was that the bacillus must be a pseudodiphtheritic one and the condition which it sets up only a false diphtheria.

Statistics of Peptic Ulcers.—Paus has compiled and analyzed some figures relating to the incidence of peptic ulcers in various continental cities. These are based wholly on autopsy reports and some of these extend back over fifty years. Facts collated are the incidence, separately of gastric and duodenal ulcers, which enables a ready calculation of the relative preponderance of the former. The author finds the percentage of duodenal ulcer remarkably constant, varying but little either way from 1 per cent., the average being about 7-10 per cent. On the other hand there was a very great discrepancy between the gastric ulcer percentages. In Cracow this was less than 1 per cent; in Prague about 1.5 in one material and 9 in another (both ancient); in Berne 3.4 (recent material); in Münich 5.16 (recent); in Jena about 9 (old), etc. etc. These fluctuations do not seem to be due to any selection resulting from the age of the statistics. The average for gastric ulcer is 3.4 per cent.; in other words, its total incidence is five times that of duodenal ulcer. The author has controlled a large material which extends over twelve years and embraces 3,000 sections. He included scars along with actual ulcers and finds in all 99 cases or 3.3 per cent. Of this number 83 (2.77 per cent.) were gastric and 22 (0.73) duodenal. His ratio was, therefore, somewhat lower than that found in published reports. It further appears that peptic ulcer is of common occurrence, and that duodenal ulcer alone is more common than has generally been believed. Duodenal ulcer is more common in males; gastric ulcer shows practically no sex element. Both affections appear at any age. There is some special tendency for peptic ulcer to be associated with disease of the cardiovascular system.

Deutsche medizinische Wochenschrift.

February 29, 1912.

Causal Relationship Between the Nose and Articular Rheumatism.—Senator relates several cases which appear to demonstrate such a relationship. In a young woman aged twenty-one a polypus was removed from a lower turbinal with the conchotome under aseptic precautions. The wound healed cleanly and the opposite side was treated in the same way and two weeks later a supplementary operation was done with the snare. From 5 to 6 days after the third operation acute articular rheumatism developed without apparent cause. It was severe in type and complicated by endocarditis. If the case were not an example of pure coincidence there should be others on record, and the author has already found two such cases in literature. To these may straightway be added others known to have occurred in connection with removal of adenoids. In one of the three cases of acute articular rheumatism following turbinectomy there had been a traumatic angina set up by the intervention. This fact is of

twofold interest. First, it shows the local presence of the cause of the blood infection, and second it serves as an example of the sequence sometimes encountered of angina and acute rheumatism. We cannot well avoid the full force of the conclusion that the infection in such cases might under more unfavorable circumstances have presented the picture not of acute polyarthritis, but of actual septicopyemia, such as has doubtless often followed operations in the nose and mouth in preantiseptic days.

Syphilitic Joint Affections.—Bering does not refer here to certain well known forms of arthropathy of luetic origin. He does not include any effects of hereditary syphilis, nor the dropsical joints sometimes seen in early syphilis, nor destructive affections due to the extension of syphilitic lesions of the epiphyses. The lesions described by him are essential, painful, and multiple, so that they would impose themselves first as examples of subacute articular or gonorrheal rheumatism. Their syphilitic nature is suggested first by the presence of a positive Wassermann reaction; second by the effects of treatment, especially with salvarsan. A history and collateral evidence of syphilis is usually forthcoming, but under the old order of things such cases would very often have been termed gonococcus arthritis, or in the absence of a history of gonorrhea would have passed readily for simple articular rheumatism. From an analysis of eleven cases the author describes this relatively new syndrome as follows: Given a history of syphilis dating back from one or two to many years, usually with a single inunction course at the time, there develops—as a rule slowly—a painful swelling of one or several joints. Locomotion is not much hindered. After some weeks there may be a sudden copious joint effusion or collections of fluid just outside the articulation. The joint structures are spared. This condition is certainly not associated with any general relapse of syphilis nor has it been preceded by such relapse. In a minority of cases, local symptoms of late syphilis coexist. As a rule the Wassermann was positive (all but one case of comparatively recent incidence and treatment). This kind of arthropathy does not differ notably from that recorded in standard works as occasionally seen in early syphilis but its status is reestablished through control by the Wassermann reaction and salvarsan. The morbid process is probably seated in the joint capsule.

Münchener medizinische Wochenschrift.

February 27, 1912.

Toxicity of Urine and Bloodserum in Eclampsia.—Von Behring and Zangemeister have conducted a joint research into these subjects at the University of Marburg. Their conclusions are extensive and perhaps far reaching. In two subjects with eclampsia during labor the toxicity of both fluids could be demonstrated on guinea pigs, the type being anaphylactic throughout including autopsy finds. The amniotic fluid was nontoxic. The toxicity of the urine and serum vanished soon after delivery, and the toxic principle in the two fluids was one and the same. The urinary toxicity was quite independent of the density, acidity, and albumin content, and the toxic principle soon disintegrated on standing. By injecting the urine into guinea pigs these could be immunized against the serum and vice versa. Even *in vitro* the serum of a healthy nonpregnant woman as well as that of a healthy gravida was able when mixed with toxic urine to disintoxicate the latter and render it powerless to poison guinea pigs. The authors do not believe, however, that eclampsia represents an anaphylactic intoxication of the pregnant woman. The clinical and autopsy finds are not of that character, which should comprise subnormal temperature, lowered blood pressure, and diminished coagulability of the blood. Some of the toxicity of puerperal urine may perhaps be attributed to involution of the uterus and other structures at the end of gestation. On the other hand, whenever the peculiar changes in the parenchyma of the liver precede eclampsia (which is the rule) the products of autolysis of the hepatic cells must load the blood with toxic principles. This has been proved in the case of one of these—lactic acid.

Diplegia Brachialis Neuritica.—Hoffmann describes three cases of this rare affection. The first case was in a boy aged nine, previously healthy, who waked one morning with both hands paralyzed. There were no sensory disturbances. Some atrophy had begun in the muscles of the hands. The patient eventually made a complete recovery. Diagnosis was made of polyneuritis of unknown origin. The second case occurred in a man of 60, alcoholic, who was similarly attacked by an apparent sleep paralysis of both arms. In this case the paralysis was painful and the nerve trunks tender to pressure. There were considerable muscular atrophy, and notable diminution of all forms of sensibility. The third patient was a man aged 25. The condition supervened in the same manner and involved both arms symmetrically. In making the diagnosis it was necessary to exclude meningeal apoplexy, lesions in or near the medulla, poliomyelitis, and Horner's nerve root neuritis.

Medicinal Ingredients of Mud.—Winckel in attempting to account for the beneficent effects of mud baths mentions the thermostatic properties, the possibility of radioactivity, the content of enzymes, nascent oxygen, mineral matter, etc. While there is abundant evidence of past enzyme action, analysis shows that ferments are no longer present. The author concludes that the therapeutic activity of mud baths rests on just two factors: The thermostatic action and certain colloidal organic matter which can determine certain reactions in the tissues by catalytic activity.

Asthma Associated with Erythematous Annular Rash.—H. Batty Shaw reports the case of a servant aged twenty-three who for five years has had attacks of asthma accompanied by the occurrence of bronchitic signs in the lungs and apparently provoked by the existence of nasal polypi; the condition is exaggerated by full meals. In each attack of asthma an annular rash appears on the body and limbs. The rash is faintly erythematous and causes considerable itching; it lasts during the attack, disappearing entirely when it passes off. Relief is given to both conditions by the use of potassium iodide. Neither the rash nor the asthma ever occurs alone. The rash has no association with the use of the various drugs employed for the relief of asthma, and was noticed in the attacks before the patient sought any relief from drugs; urticaria is not a feature of the skin eruption.—*Proceedings of the Royal Society of Medicine.*

Sclerosis of the Ovarian Vessels.—C. Decio has examined the ovaries of twenty individuals from fifteen to fifty-five years of age with reference to the presence of changes in the ovarian vessels. He finds that in infants the structure of the vessels is normal, while in adults and old women there are present extensive vascular alterations which are of three types. The first type consists of changes in the vessels of the hilum, involving the intima, and of the nature of sclerosis; also in the cortex there occur changes involving the internal coat, characterized by destruction of the muscular layer and its substitution with hyalin connective tissue and an elastoid substance similar to normal elastic tissue. The second type of change is similar to the normal involution of the corpora lutea, not pathological, and probably due to the same cause as that of involution. The third type of change is a true vascular sclerosis, not hyperplastic in character, but degenerative.—*Folia Gynecologica.*

Insurance Medicine.

PERSONAL FACTORS IN LONGEVITY.

Among the many factors which tend to prolong life, one of the most important is the knack of longevity, that is, one must be descended from ancestors whose span of existence has been beyond the ordinary. It is, however, equally important that in order to attain old age a person should conduct his life reasonably in consonance with the laws of health. Excesses in athletics, in sedentary work, and in eating or drinking are one and all antagonistic to long life. In the *Dietetic and Hygienic Gazette*, February, 1912, A. H. Stewart emphasizes the importance of family history in considering an individual's chances of becoming old and alludes to the fact that insurance companies place considerable weight upon this family history.

Sir Benjamin Richardson attempted to formulate a working hypothesis by means of which one might estimate longevity upon the basis of heredity. He was of the opinion that a fair approximation can be reached by adding together the number of years attained by the parents and grandparents of an individual and dividing the result by six. The quotient would be the approximate life expectancy of the individual. The death of a parent is considered by insurance companies to be of much greater significance than the death of a brother or sister, and consequently the endeavor is sometimes made to find out which parent an applicant resembles more closely. The age of a person's parents at the time of his birth is looked upon as a matter of considerable moment in estimating the expectation of life. Children born of fathers who are between twenty and forty years of age or mothers who are between twenty and thirty-five seem to have the best chance of survival, while children born of fathers who are past forty or mothers who are under twenty possess a poorer chance to survive.

The second, third, fourth, and fifth children are thought to have a better prospect of longevity than the firstborn or those born after the fifth child. However, according to Stewart, recent statistics seem to indicate that one's position in the numerical order of the family is not as important as the age of the parents, especially of the mother, at the time of birth. In fact, about 25 per cent. of centenarians whose family histories have been traced were firstborn children. If the children of primiparæ are smaller and less vigorous than those of multiparæ, as has been claimed, this fact is to be attributed probably more to the difference in the age, size, and physical vigor of the mothers than to the number of births. Still there appears to be a valid physiological basis for the belief that children born of mothers who mature early are larger and stronger than those who mature late, and also for the belief that the members of large families are likely to live long, since the begetting of large families indicates a special physical vigor of the parents. There appears to be no question as to the intimate relationship between the size of the mother and that of the child.

As to the comparative longevity of different races the conclusion is reached that the chief factors in longevity are an inherently strong and enduring physical organism, outdoor occupations without undue exertion or exposure, a simple and nutritious diet, temperance in all things, and a cheerful disposition. The prime personal factor is unquestionably an inborn quality of steady nutritive force, characterized by the powers of endurance, resistance, and recuperation. Excessive alimentation is responsible for the shortening of thousands of lives. The average intelligent workingman, whether in the store, the factory, or the field, is generally guided by instinct to the most wholesome and nutritious diet. This is not the case with many of those of sedentary habit, particularly among the affluent, whose instincts and appetites have been perverted by overindulgence in rich and highly seasoned food. There are those who assist with their teeth in digging an early grave, while the speed at which American business is being conducted is charged with being an important factor in shortening the span of life.

It is finally pointed out by Stewart that barring inherent weakness and unavoidable accidents, an individual's sojourn on the globe is largely within his own keeping. Although insurance companies are no less solicitous than formerly regarding the life history of one's antecedents, they are more exacting than ever with regard to an applicant's occupation and habits of life.

ACCIDENT COMPENSATION LAWS IN FRANCE.

(From a Special Correspondent.)

The laws in France regarding workingmen's compensation are well drawn up and certainly provide liberally for the workingman during his temporary or permanent disability which may ensue from any accident occurring to him while he is at work. We shall merely give a résumé or abstract of the principal points covered by the act and quote some ratings of compensation given for the enforced cessation of occupation due to accidents.

The workman must be incapacitated for four days before he comes under the Compensation Act and then he receives compensation accordingly. If his annual wages amount to 2400 francs (about $475) and he is permanently disabled and unfit to continue his work he receives an annual compensation equal to two-thirds of the amount of his former wages. Should he be permanently partially disabled so that he cannot carry on his work as he did previous to his accident and is thus forced to gain a lower wage than formerly, he receives compensation amounting to half of the difference between the wage he formerly received and the wage which he now earns. During temporary disability he receives compensation equal to half of his salary, pay being included for Sundays and holidays. If the wage is a varying one, that is, payment by hour-work or piece-work, the workman receives half of his *average* wages.

In case of death from accident the widow receives 20 per cent. of her late husband's wages and various stipulations are made for the children, but in all the compensation must not exceed 40 per cent. of his total wages.

The provisions made for medical attendance are adequate and the fees for various medical services are plainly and exactly stated and cover the different points carefully. Medicinal treatment is also covered, and there is a special fixed tariff for the drugs. We shall merely point out for comparison the different medical charges permissible under this act.

When the doctor visits the patient he receives 2 francs as a fee. In Paris the fee paid is 2.50 francs, and where the fee was 2.50 francs before the law of 1901 stipulated 2 francs per visit, 2.50 francs

can still be charged. In localities with less than 5000 inhabitants the doctor's fee is 1.50 francs per visit. If the patient visits the doctor at his office the fee is decreased 50 centimes. The visit to the doctor includes one bandage and light dressing in the fee, but the medical man has the right to charge for the *first* bandage and dressing.

Between the hours of 9 P.M. and 6 A.M. three times the ordinary fee can be charged. Each half-hour spent at the house is equal to a fee of an extra visit with maximum of five half-hours in serious cases. If a doctor is called in consultation he can charge a fee equal to four visits. Medical certificates given by the doctor are paid for at the rate of 2 francs for a short certificate and 5 francs for a complete report.

Oculists receive 3 francs per visit; 5 francs for a slight operation such as removal of a foreign body from the cornea. For a cataract extraction or for an enucleation 75 francs (about $15) is the fee. Otorhinologists receive 5 francs per visit and 10 francs for a complete examination. These notes may furnish the home practitioner with an idea of the chief points covered by accident insurance laws in France at the present day. Though the medical fees are not high, there is a good medical service with fixed tariff at hand for workmen and in the larger towns the hospitals of course are always open and ready to receive patients night and day.

Municipal Life Insurance.—A despatch to the *New York Times* from Berlin states that the City Council has referred to a special committee a project for establishing a system of municipal life insurance. The Province of Brandenburg, wherein Berlin is situated, recently introduced public life insurance, which appears to be working so satisfactorily that the Berlin City Government has now been induced to look into it. The scheme is mutual, all the profits being divided among the policy holders.

Life Expectation of Diabetics.—Feilchenfeld quotes Florschütz, who said that the presence of sugar in the urine is the most disturbing symptom in an applicant for insurance and takes rank only with hemoptysis. Yet our present authorities give a good prognosis for diabetics. V. Noorden says that change from a mild to a severe form of diabetes should not occur if the treatment is properly carried out. If the disease is recognized early no other sickness is so easily controlled. These views have completely changed the status of diabetics as risks, and the kind of diabetes is the deciding factor in judging them. Glycosuria may be artificial, that is, may occur in perfectly healthy persons; it may be alimentary; it may be due to a disturbed nervous system, etc., and it may be diabetic. Artificial or pseudoglycosuria may depend upon the reduction of the usual test solutions by such substances as creatinin, pyrocatechin, turpentine, ether, chloroform, chloral, amyl nitrite, etc., that may find their way to the urine. Alimentary glycosuria should, of course, be judged by proper test meals. Symptomatic glycosuria usually leads to rejection of the applicant because of the causal organic disease, yet such a glycosuria may disappear with the disappearance of the original illness.

Feilchenfeld has collected 122 cases of light forms of diabetes. Of these, 90 were male and 32 female patients. The majority of the patients belonged to the well-to-do classes of society and to the city population.

Feilchenfeld's figures show the great increase of diabetes among Jews, yet he thinks that social rather than racial characteristics explain this well-known fact. The Jews are frequent patients in private clinics, from which statistics have emanated. They often lead a sedentary life, consume much fat and sugar in their food, and are apt to suffer from disturbances of the nervous system.

Thirty per cent. of the patients were alive ten years after the discovery of sugar in their urine, and many physicians thought that their patients were good risks for a limited insurance. The greatest number of the patients were capable of continuing at their usual occupations. Most of them were persons of large stature and obese. As causes of the disease nervous excitement, heredity, syphilis, and infectious diseases were named in this order. Of the complications arteriosclerosis, albuminuria, neuralgia, and pruritis were the most frequent. Most of the patients showed marked improvement with treatment, as evidenced by the disappearance or diminution of sugar in the urine.

Feilchenfeld concludes that persons with light forms of diabetes are insurable for a limited number of years if certain precautions are taken. Hereditary diabetes should speak against such insurance. The age of the applicant should not be below thirty-two years. Arteriosclerosis and any other additional organic disease should be excluded. The sugar tolerance should be high, and careful tests should be made to show this. Insurance for fifteen to twenty years should be advisable in such cases.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, January 1, 1912.

Progressive Paralysis and the Reaction of the Pupils.—Freund saw twenty cases of progressive paraylsis in two hundred cases of sickness, among persons insured against total disability. This ratio is greater than the usual ratio of paresis and is explained by the greater prevalence of this disease among the intellectual classes that take advantage of such insurance. Paresis is of great importance from the standpoint of insurance because of its frequent appearance in otherwise healthy persons and the few diagnostic signs it may show in its incipiency. Care should be taken to look for a history of syphilis followed by neurasthenic symptoms. Convulsions, temporary hemiplegia, even frequent vertigo should be looked on with suspicion, once syphilis and neurasthenia coexist in an applicant. The pupillary phenomena are of the greatest importance, for they often precede other signs of disease by several years. Difference in the size of pupils is of greater importance than simply contracted pupils, for the latter occur in health. Of course, care must be taken to have equal illumination of both eyes in looking for this sign.

Still more important is the Argyll-Robertson pupil, which occurs in two-thirds of all cases of general paralysis. Several sources of error must be here estimated. The patient's eyes should not be exposed to strong light just before looking for the Argyll-Robertson phenomenon; he should stand with his back to the window or in a dark portion of the room. The difference between illuminating the pupils and leaving them in the natural light should be considerable, for miotic pupils especially may show very slight contraction only on small degree of illumination Consensual reflex must be guarded against by covering the eye that is not being tested. Sluggish reaction should call for an examination in a darkened room with artificial light and a convex lens. The patient should direct his gaze at the distance so that accommodation may not simulate contraction to light. Sluggish reaction is suspicious not because of the degree of contraction but of the promptness of its appearance and the quickness of the contraction. The Wassermann reaction should be made use of in doubtful cases, and it is to be hoped that insurance examiners will avail themselves of it to a greater degree than is done at present.—*Blätter für Vertrauensärzte der Lebensversicherung*, September and October, 1911.

Book Reviews.

TEXT-BOOK OF MEDICAL JURISPRUDENCE AND TOXICOLOGY. By JOHN J. REESE, M.D., late Professor of Medical Jurisprudence and Toxicology in the University of Pennsylvania; late President of the Medical Jurisprudence Society of Philadelphia. Eighth edition, revised by D. J. MCCARTHY, A.B., M.D., President of Medical Jurisprudence (George B. Wood Foundation) in the University of Pennsylvania; Neurologist to the Philadelphia General and St. Agnes Hospitals; Consulting Neurologist to the Henry Phipps Institute, the State Asylum for the Insane, Norristown, Pa., and the Phoenixville Hospital. Price $3.00 net. Philadelphia: P. Blakiston's Son & Co., 1911.

THIS book has long been popular with medical students. It is probably the most serviceable of the smaller manuals on the subject; and it contains the essentials of medical jurisprudence in clear language and concise form. The last three or four editions have been under the editorship of a chemist; the present edition has been revised by a neurologist. Various alterations have been made in the text, and a few additions have been incorporated; but the general character of the volume remains as before. The chief changes are to be found in the chapter on insanity, and a short account of the method of commitment of the insane has been inserted.

THE CRIMINAL AND THE COMMUNITY. By JAMES DEVON, Medical Officer of H. M. Prison at Glasgow. With an Introduction by Professor A. F. MURISON, LL.D. Price $1.75. London: John Lane, The Boley Head; New York: John Lane Company, 1912.

A DISTINCTIVE merit characterizes this book among the many on a similar theme that have appeared within the past year. It breathes a personal note, for the author as medical officer of a large city prison speaks of what he has learned at first hand from personal observation. The social causes of crime are portrayed with a freedom of brush only possible to one who has been brought up from early childhood among the people who toil, who has seen the distress engendered by want and the baneful influences of overcrowding. It is society's responsibility in the evolution of the criminal that the author emphasizes in this work. The rôle of heredity, of insanity, and physical defects are pointed out so far as they influence the production of the criminal. The influences of drink, of poverty, immigration, social conditions, age, and sex are all graphically pictured. The rationale of punishment, the machinery of the law, the prison system, the prison and its routine, variations in routine, the prisoner on liberation, the inebriate home, the prevention of crimes act, the family as model, alternatives to imprisonment, and the better way, form the titles of most illuminating chapters. The author presents views on the subject of penology that will not fail to awaken discussion. These views are extremely original. It is pointed out that all modern systems of penology are more or less a failure. The author would substitute for confinement in many cases a system of boarding out prisoners under the supervision of responsible guardians, somewhat after the manner of boarding out the insane, as practiced in certain colonies abroad. "If we would make the best of him," says Dr. Devon, "we should restrict the liberty of the offender as little as possible consistent with the well being of the community, and enlarge it gradually as reason is shown for doing so. We cannot injure him without injuring ourselves, and we ought to set about to make the best rather than the worst of him."

MINOR SURGERY. By LEONARD A. BIDWELL, F.R.C.S., Surgeon to the West London Hospital, Dean of the Post-Graduate College, Consulting Surgeon to the Blackheath and Charlton Hospital and to the City Dispensary, and author of "Handbook of Intestinal Surgery." With eighty-eight illustrations. Price $2.00. London: University of London Press; Hodder & Stoughton & Henry Trowde, 1911.

THERE is a distinctive feature about this small manual of 265 pages, namely, its simplicity and the limitation of its subject matter to the few definite surgical procedures that should be mastered by the general practitioner no less than by the surgeon. The technique in minor surgery, the minor operations, the injections, the minor surgery of the urinary tract and of the rectum, the preparation and use of plaster-of-Paris splints, the preparation for an operation in a private house are among the subjects fully and yet succinctly described by the author. The originality of the latter's methods are perceived in the suggestions for the treatment of epistaxis, bleeding from a tooth socket, for hemorrhage after removal of the tonsil, for removal of a ring from a swollen finger, etc. The book may be recommended to the student and practitioner as a practical guide in minor surgery, that may be read at one sitting and kept for future reference.

ARZNEI UND DIÄTVERORDNUNGEN für die gynäkologische Praxis. Aus der Frauenklinik von Prof. Dr. PAUL SIRASSMANN in Berlin. Price 1.60 marks. Berlin: Verlag von August Hirschwald, 1912.

THIS pocket formulary with a marginal index has been prepared by the author with the view of giving wider circulation to the medicinal and dietetic measures that have been tried out in his clinic for many years and taught to his students. The simplicity of these measures, the wide scope of their application, and the ease with which they may be consulted render this manual one which the general practitioner no less than the gynecologist will find exceedingly useful in his daily work.

HANDBUCH DER HYGIENE. Unter Mitwirkung von R. ABEL, Berlin; J. BOETHKE, Berlin; C. FRÄNKEL, Halle; E. FRIEDBERGER, Berlin; U. FRIEDEMANN, Berlin; N. A. GINS, Frankfurt a.M.; E. GOTSCHLICH, Alexandrien; R. GRASZBERGER, Wien; O. HEUBNER, Berlin; F. HUEPPE, Prag; K. KISZKALT, Berlin; R. KOLKWITZ, Berlin; G. LANGEN, Berlin; K. B. LEHMANN, Würzburg; A. LODE, Innsbruck; O. MARCH, Charlottenburg; J. MAYRHOFER, Mainz; S. MERKEL, Nürnberg; P. T. MÜLLER, Graz; M. NEISSER, Frankfurt a.M.; W. PRAUSNITZ, Graz; H. RÄUBER, Erfurt; H. RECKNAGEL, Berlin; C. REICHLE, Berlin; A. SCHMIDTMANN, Marburg; H. SCHNEIDER, Berlin; M. SCHLOTTELIUS, Freiburg i.B.; O. SPITTA, Berlin; H. THIESING, Berlin; K. THUMM, Berlin; T. v. WASIELEWSKI, Heidelberg; W. WEDDING, Berlin. Herausgegeben von Prof. Dr. M. RUBNER, Geh. Medizinalrat, Berlin; Prof. Dr. M. v. GRUBER, Obermedizinalrat, München, and Prof. Dr. M. FICKER, Berlin. I. Band. Mit 134 Abbildungen und 1 Tafel. Price 27 marks. Leipzig: Verlag von S. Hirzel, 1911.

THE monumental character of this work, of which the title "handbook" is but the modest German substitute for the term "treatise," has already been alluded to in these columns, when the second part of the second volume was reviewed. The first volume contains the following topics: introduction, by M. v. Gruber; the history of hygiene, by M. Rubner; the science of metabolism and nutrition, by M. Rubner; foods and delicacies, by J. Mayrhofer; the atmosphere, by A. Lode; the hygiene of the oil, by W. Pransnitz; warmth, by M. Rubner; clothing, by M. Rubner; exercises, by F. Hueppe; and climate, by A. Lode. It is almost superfluous to state that each of these subjects is exhaustively treated, in the manner so characteristic of German authors. The student of preventive medicine, the sanitarian, and the public health officer cannot afford to be without this work, which treasures the latest and best in hygienic science.

SOZIALE PATHOLOGIE. Versuch einer Lehre von den sozialen Beziehungen der menschlichen Krankheiten als Grundlage der sozialen Medizin und der sozialen Hygiene. Von Dr. med. ALFRED GROTJAHN, Berlin. Price 18 marks. Berlin: August Hirschwald, 1912.

SOCIAL pathology, or the economic or sociological aspects of disease, is a subject that has awakened considerable attention within recent years, particularly in Germany. The inauguration of state insurance with the large number of *Krankenkassen* and a multitude of trained statisticians has rendered possible the accumulation of data which, in addition to those already known, have been utilized by the author in the preparation of this volume. Naturally, the discussion of tuberculosis comes in for considerable attention. The various other acute and chronic diseases are analyzed with reference to their sociological significance, and extended discussion is given to the subjects of criminal abortion, prophylactic abortion, and the restriction of offspring. Alcoholism, prostitution, infant morbidity and mortality, and the mental diseases are topics whose social significance is clearly shown. He whose medical interests are not restricted by the study of individual patients, but extend to the ever widening horizon of humanity, will find this book an excellent text upon which to base his studies. The volume is a tribute to German scholarship, with its thoroughness and utilitarian affinities. The bibliography which the author has collected and has indicated in the footnotes on almost every page is already an enormous one, and great, indeed, must have been the author's labor in picking out the kernels for our benefit.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK

Stated Meeting, Held February 26, 1912

THE PRESIDENT, DR. CHARLES GILMORE KERLEY, IN THE CHAIR.

Good Showing for the Year 1911.—DR. KERLEY announced that during the year 1911, 99.3 per cent. of the members had paid their dues, making the Society a banner Society with a larger paid up membership than any other county society in the State. The Medical Society of the County of New York now had a membership of about 2,400. It was 116 years old and he thought it made a remarkable showing.

Executive Session.—By-Laws, Chapter XV, Art. 1, was made to read as follows: "The Executive Session shall be limited to one-half hour. If business of sufficient importance is brought before the Society to warrant the extension of time of the Executive Session, such time limit may be extended by a majority vote of the members present." By-Laws, Chapter XV, Art. 2, was made to read as follows: "No address or paper read before the Society, except those by the president and orators, shall occupy more than twenty minutes in its delivery, and no member shall speak upon any question before the house for longer than five minutes nor more than once on any subject, except by the consent of the Society."

The scientific session was devoted to a symposium on perineorrhaphy and with lantern slide demonstrations.

Etiology of Perineal Laceration: Indications and Technique of Primary Perineorraphy.—DR. J. CLIFTON EDGAR read this paper. He considered the factors which bore directly and indirectly upon the causation of pelvic floor lacerations under four major classes, namely: 1. Anomalies of the expulsive forces. 2. Anomalies of the soft parts. 3. Faulty presentations of the fetus. 4. Faulty posture of the mother. In regard to the fourth factor, he stated that long observation had convinced him that extraction of the head at the outlet with the patient in the exaggerated lithotomy position conduced to unnecessary injury of the pelvic floor. At the moment of extraction or expulsion of the head, the patient's thighs should be brought down into the ordinary dorsal or "cross bed" posture. Moreover, the delivery of the head through the pelvic outlet with the forceps still applied was usually unnecessary and favored laceration. After considering the time when it was advisable to repair these lacerations and the technique that he employed, the writer concluded as follows: 1. More attention should be given to the causes and prevention of perineal lacerations as in this way many perineorrhaphies would be avoided. 2. Broadly speaking, all lacerations were best closed at the time of labor, but in those accompanied by bruising, edema, and swelling the best results were obtained by waiting a few hours or a day or so until conditions were more favorable. Tears involving the rectum should be treated more deliberately, due time being given for the nutrition of the parts to improve, for the patient to recover from the shock of labor, and for the securing of assistance and conveniences. 3. In all cases before suturing the torn surfaces should be cleansed and the edges occupied with tenacula in order to determine their precise relationship. 4. The sutures should not be drawn too tight, as they would cut through the tissues. 5. Chemical antiseptics should be avoided. 6. An assistant should be procured to administer the anesthetic; ether should not be entrusted to a nurse unless she was trained in its use. Ether should be used and not chloroform. 7. In rectal tears, sutures substituted in the rectum gave better results, the wound being less likely to become infected than when buried sutures were knotted on the vaginal side of the laceration. 8. In primary perineorrhaphy interrupted sutures for the vaginoperineal lacerations gave better results than the buried layer suture. As to the after treatment, the knees should be loosely bound together and the use of the catheter should be avoided, if possible. Thorough cleanliness of the external genitals should be maintained, but no douche should be used unless the lochia become putrid. The bowels should be made to move after the second day by an injection of oil and an enema should be entrusted only to an experienced nurse. In the passage of a vaginal or rectal tube, the greatest care should be exercised not to disturb the sutures.

Perineorraphy in Principle and in Practice.—DR. ARNOLD STURMDORF presented this communication. After quoting from several authorities to show that there was a general acknowledgment on the part of gynecologists that the principles and practice of perineorrhaphy demanded a radical revision, he stated that the sum and substance of the whole problem was contained in the statement made by C. M. Watson that the classical operations for the secondary repair of the torn or relaxed perineum had been successful only to a degree; and that the more extensive the injury to the levator muscle, the less effective these operations. The keynote in the clinical significance and therapeutic indications of perineal lacerations was the existence of prolapse. This presented itself in two forms: first as a simple ectopia of the relaxed and redundant vaginal mucosa which was curable by any of the usual procedures; secondly as a true hernial descent of the pelvic contents which could not be permanently cured by any such procedure, substituting as it did, mechanical obstruction in the form of a cicatricial wedge at the vaginal outlet for the physiological retention exercised by the muscular contractility in the pelvic floor. The perineal musculature should not be conceived as presenting simply a sphincter at the vaginal outlet, not as a mere muscular bottom passively supporting the weight of the superimposed pelvic organs, but as an active integral part in a complicated mechanism that counteracted the expulsive force of intra-abdominal pressure by mechanically deflecting that pressure in the direction of the normal outlets. In order to elucidate this mechanism the writer applied the laws of dynamics and from a careful observation of their bearing on the problem involved he showed that the function of the levator might be summarized by saying that its contraction diminished the force of intraabdominal pressure upon the pelvic contents by directing its course, and increased the resistance to that pressure and closed the outlet against that pressure by narrowing the uterovaginal angle and compressing the vaginal canal. A study of the extrusions resulting from perineal lacerations revealed elements closely analogous to those of inguinal hernia. Both conditions resulted from muscular insufficiency over a vulnerable situation; both tunneled their outward course along potential channels in the abdominal parietes. The levator ani muscle, embracing the abdominal floor, was as much an abdominal muscle as the rectus, obliquus, or transversalis; the form and nature of the muscular arrangement controlling the inguinal openings above the pubes presented the exact counterpart of the levator arrangement beneath the pubes. The fully developed cystocele was a complete hernia, differing from inguinal hernia only in that the bladder and vaginal wall entered into the formation of its coverings. In the same manner the rectocele presented a hernia of Douglas' pouch. The radical cure of inguinal hernia became possible only with the recognition of the necessity of restoring the contractile muscular resistance to the hernial area and of obliterating its perineal funnel; in other words the muscular and serous planes involved were so constructed as to reestablish the normal deflection of intraabdominal pressure. The application of this principle to perineorrhaphy by a method of levator interposition and suture had been submitted by the

writer seven years ago and the operation might be described as comprising four essential steps: 1. Exposure of the seat of the lesion. 2. Mobilization of the levator muscles. 3. Sutural interposition of the muscle. 4 Readjustment of the superficial coverings. Preliminary to the first step the pelvic contents should be replaced into their normal position and the retractor levator bands located on each side. The vaginal mucosa was separated by hooking a tenaculum on each side of the vaginal orifice into the tissues just external to the lower caruncles and another into the center of the posterior mucocutaneous margin; by traction on these three points, a triangular flap was outlined which was elevated to the crest of the rectocele but not removed. Surgically the levator segments constituted one muscle bundle about one inch in width and three-eighths of an inch thick behind each pubic ramus. The vaginal flap being reflected upward, a finger or closed scissor was thrust into the narrow lateral chink, which was distinctly palpable on either side between the inner edges of the ramus and muscle, and the latter bluntly liberated from its fascial and cicatricial surroundings along the whole extent of its outer circumference, preserving its median coverings as far as possible. This mobilization should not split the muscles and should be sufficient in extent to permit a broad approximation of the corresponding bands without tension. Occasionally the internal pubic artery demanded ligation but otherwise the free bleeding was largely venous. From three to four interrupted chromic gut sutures coapted the muscles and closed the gap in front of the rectocele; the sutures should not be passed through but entirely around both muscles so as to secure the broadest possible surface contact under the vaginal floor. The uppermost suture was inserted just high enough to normally appose the lower to the upper vaginal wall. In readjusting the superficial coverings no vaginal mucosa was sacrificed; the transverse wound was converted into a perpendicular slit by properly applied traction and the edges united side by side by interrupted or continuous sutures. From the tip of the vaginal flap to the caruncles, the suture included the vagina mucosa only, while from this point downward each stitch gathered the skin and all the fascial layers superficial to the muscles which were drawn from under the edges of the wound toward the median line. The little comb of vaginal mucosa thus formed dropped into the vaginal canal to be converted into a rugous fold; the introduction of a narrow strip of gauze to absorb the first oozings completed the operation. Active experience covering a period of ten years with this operation had shown that a strict adherence to the technique outlined would yield results which, three months after operation, made it impossible to distinguish the previously lacerated perineum from the normal both in form and function.

The Treatment of Prolapsus of the Uterus, with Attendant Cystocele and Rectocele.—Dr. J. RIDDLE GOFFE read this paper. He stated that the results obtained by operations for this condition had not been permanent because the operations were not based upon correct dynamic principles. He contended that normally the ligaments were the supports of the uterus and bladder, being supplemented by the pelvic floor only when subjected to excessive but temporary intraabdominal pressure. In resisting this pressure these ligaments, by their reciprocal and interdependent action, tilted the uterus and its broad ligaments in such a way as to deflect intraabdominal pressure, and thus avoided its direct line of action. A nice balance existed between muscular action of the abdominal walls and the musculature of the pelvic floor together with the ligaments of the uterus which received, deflected, and distributed this force in such a way as to direct the resultant into the line of expulsion and at the same time tended to preserve visceral support and equilibrium. In the operation which he had devised for the relief of procidentia with rectocele and cystocele, it had been his design to shift some of the responsibility for success in these operations from the floor of the pelvis to the ligaments of the uterus and bladder, thereby invoking nature's plan of holding organs in place by suspension. The responsibility for supporting the rectum and assisting in its functions still rested with the levator ani muscle and its fascia. He had always laid stress upon the restoration of the levator ani muscle as the essential factor in restoring function to the floor of the pelvis and in securing permanency of results. He was convinced that these results could be best obtained by actual exposure and direct union of the limbs of the levator ani muscle, stitching them together by buried sutures in front of the rectum in accordance with the method described and practised by Dr. Sturmdorf. From the operative standpoint these cases could be divided into two classes, those in women of the child-bearing age, and those in women at or after the menopause. In the first class it was necessary to preserve the uterus. In operating on this class the first thing he did was to curette the uterus and to amputate the cervix. A transverse incision was then made through the vaginal wall in front of the cervix, and through this the bladder was dissected from the uterus up to the peritoneal reflection. The peritoneum at the line of reflection was torn across widely from side to side out onto the broad ligaments. The bladder was dissected from the vaginal wall by means of a blunt dissector, the dissection extending to the urethra and reaching out to the limits of the bladder on either side, the bladder thus being freed from all its inferior attachments. An incision was then made through the vaginal wall throughout its entire length from the middle of the transverse incision up to the urethra. With an anterior retractor the bladder and the vaginal flaps were lifted up behind the symphisis and the fundus uteri turned down into the vagina. This brought the appendages into view. The round ligaments were then shortened by doubling them on themselves and the loop made fast to the uterus at the anterior origin of the round ligaments. Three chromaticized catgut ligatures, No. 2, were passed, one through the anterior wall of the uterus at its middle point and the other two through the anterior wall of the broad ligaments just outside the lateral margins of the uterus. These were left long and protruded through the vulva. A point was now selected in the base of the bladder at such a distance from the urethra as when carried up to the point of insertion of the first three ligatures would cause the base of the bladder to make a straight line from the urethra to the uterus. Through this the suture was passed, catching up in its course the bladder attachment of the peritoneum where it was torn from the uterus. Two points in the base of the bladder were now selected at either side of the first selected point and distant from it an inch to an inch and one-half. Through these points the lateral sutures were passed respectively. The three were then tied beginning with the middle one. The first one took up all the slack in the line from the uterus to the urethra, but made a ridge in the interior of the bladder with a sulcus on either side. By tying the lateral sutures, however, these sulci were obliterated and the base of the bladder was spread out upon the anterior face of the uterus and broad ligaments. The overstretched fascia and wall in the anterior vagina was now cut away to such a degree on either side of the median line that when stitched together it would fit snugly under the base of the bladder. This relieved the hernia and restored the support which the bladder received from the fascia lata, on either side. The vagina was then stitched to the uterus at points that would smooth out the anterior vaginal wall, but would not shorten it to a degree that would cause it to pull on the cervix. The transverse suture in the

vaginal wall was closed with a running suture. The floor of the pelvis was reconstructed in accordance with the method described by Dr. Strumdorf. The cases of the second class that were found in elderly women were the most severe and unmanageable. The principles of the operation were the same as in the minor cases, but the pelvic tissues having become atrophic, thin, and friable they were useless as supports and consequently a vaginal hysterectomy was done. To provide a support for the bladder, he stitched together the broad ligaments from the round ligaments down to their bases, taking in sufficient slack to make them draw taut across the pelvis. Upon this plane of tissue the base of the bladder was spread out and fastened, following the technique already described. The anterior wall of the vagina was cut away as before, its edges stitched together, and the upper end stitched to the broad ligaments. In addition to restoration of the levator ani muscle, the rectum was plicated upon itself by inserting a line of buried sutures across the anterior wall, passing the stitches parallel to the longitudinal axis of the rectum. The floor of the pelvis was then restored and colporrhaphy done throughout the entire length of the posterior vaginal wall. Dr. Goffe said that he had been doing this operation for nine years. In two cases before he began plication of the rectum a high rectocele came down over the perineum and presented at the vulva. In no instance had the uterus or bladder failed to remain in position and in no case had there been any infection to mar the permanent healing of the tissues. It was his custom to insert a small gauze drain between the bladder and the vaginal wall in cases that bled unduly from the raw surfaces. He had used the operation of interposition of the uterus between the bladder and the vaginal wall in the early stages of prolapsus and had found it satisfactory. At a recent operation of this kind there was a constant tendency for the fundus to slip out through the vulva and the operator had difficulty to keep it in while he stitched together the vaginal wall in front of it. The question was did the uterus hold up the vaginal wall, or the vaginal wall the uterus. The only criticism that had been offered to his operation was that it was complicated and difficult, but to a skilled gynecologist an operation that promised such assured results should not be considered too difficult.

Dr. George L. Brodhead agreed with Dr. Edgar that one of the most frequent causes of laceration of the perineum was the too rapid advance of the fetal head and it was naturally a matter of judgment and experience to tell when this advance should be checked. As a rule when the perineum was about to tear it became white, or the fourchette became dry and apparently brittle. There was no doubt in his mind that the exaggerated lithotomy position was a very frequent cause of perineal lacerations. With regard to prophylaxis, in operative work the feet of the patient should be supported by stirrups rather than by the usual leg holders; the soft parts and the tissues at the outlet were then not so much on the stretch and were less liable to tear. When the head was beginning to distend the outlet, a small table should be placed at the foot of the operating table so that the patient's legs could be taken from the stirrups and allowed to rest upon the table. In this way the soft parts were relaxed and a place was provided for the child. Episiotomy was also a very important factor in prophylaxis. Dr. Brodhead said he had long since become convinced of the value of this procedure and had made use of it in many instances and he had never seen a complete laceration of the perineum in vertex cases; he attributed this to the fact of the performance of episiotomy. The complete tears which he had were all in the breech cases. The immediate repair of the perineum should not be adopted; these patients were sometimes exhausted by a long labor and, perhaps, they had lost much blood, and in many instances there was insufficient light. Better results would often be obtained if the operation was deferred until the following day when proper preparation could be made for a successful operation.

Dr. Brooks H. Wells said that in secondary repair of the perineum the methods used to-day had been evolved from the work of the older operators. The suture of the levators had been suggested by Hadra in 1884 and by many since that time. He had always taught the necessity for approximating the levator edges and restoring the central attachments to the transverse perineal muscles and had obtained clinically and anatomically very satisfactory results in the restoration of the lifting function without drawing the levators from their sheaths.

Dr. George Gray Ward said he was pleased at the beautiful description of the work done by Dr. Sturmdorf, a work that he had been doing for many years; his own method was based on the same principles and his results were about the same.

Dr. LeRoy Broun did not believe that Dr. Sturmdorf went far enough with his sutures in his attempt to repair the damaged parts. Before the American Gynecological Association many years ago, Dr. Emmett brought out the fact that in operating they did not attend to the separated fibers of the levator ani muscle on both sides and, therefore, as a rule, perineal tears occurred in subsequent labors. Dr. Emmett advised all to take up the torn ends of this muscle with its fascia and to bring them back and fasten them in their original place. This operation had stood until the present day. One should be concerned not only with the levator ani muscle, but with its fascia as well. Emmett's operation should not be entirely discarded today.

Dr. John Van Doren Young said that it seemed to him that the papers and the discussion illustrated the fact that there were a large number of men in the general profession, as well as in specialties, who could learn a great deal from what had been presented. There was one point that had not been really gotten hold of, a picture of the complex of the situation, which was the condition they were trying to relieve, and the solution of which was to be found in a study of the anatomy of the parts. It should not be forgotten that the levator ani muscle played a very important part in this work, and its proper adjustment should be attended to.

Dr. Austin Flint, Jr., said that it was his habit, when the head was about to be born, to bring the knees together. The lacerations of the perineum which occurred were due in large part to a distention of the perineum downward and this could be lessened by such a procedure. Pushing the perineum back would save many of them. With regard to episiotomy it was necessary to know just when to perform this operation. Unquestionably in his hands it had saved a great many complete tears. Dr. Flint had done the operation described by Dr. Sturmdorf many times, with certain modifications, and these consisted in adhering to the original principles of the Emmett operation, working at the upper edges of the levator ani muscle, bringing the parts together and securing them in place.

NEW YORK ACADEMY OF MEDICINE.

SECTION ON MEDICINE.

Stated Meeting, Held February 20, 1912.

Dr. W. L. Niles in the Chair.

Acrocyanosis in a Case of Tricuspid Disease.—Dr. Jesse Godfrey M. Bullowa reported the case of a young man, twenty-three years old. Four years ago he began to have nocturnal attacks of indigestion and precordial pains which were thought to be due to smoker's heart. During the summer and fall he commenced to have blueness of the distal phalanges and the index and middle fingers of

the hands, which extended as far as the wrists. During the summer there was a blue mottling of the fingers when the patient exercised; during the winter, however, the circulation was restored by exercise. Three years ago, while a student at Princeton, he had an endocarditis which followed rheumatism, chiefly with pain in the shoulders. He had a very rapid pulse, 158. His temperature was 102° F. He had frequent attacks of sore throat. In January a systolic murmur was noticed over the ensiform; there was a blood pressure of 110; the specific gravity of the urine was 1014. In May there were no murmurs, the pulse was 72 and regular. A diagnosis was made of tricuspid disease. The heart was enlarged to the right by percussion, orthodiagram and teleröntgenogram. On auscultation there was found a systolic roughening, at times a presystolic murmur, and a diastolic blow which was most intense just to the right of the fourth chondrosternal junction and over the ensiform cartilage. The blowing murmur was transmitted to the liver area and to the vessels of the neck when the breath was held in inspiration, and over the lungs during apnea. A polygraphic tracing showed an auricular pulse in the jugular and in the liver. The areas of hyperalgesia were studied. The patient improved under exercise and restricted fluids.

The Use of Bouillon Cultures of Staphylococcus Pyogenes Aureus in Diphtheria Convalescents and Bacillus Carriers.—Dr. R. G. WIENER read this paper the object of which was to call the attention of the profession to this procedure, which was still in the experimental stage, in order that it might be further tested. Some years ago a Danish physician, A. Schiotz, observed that during an epidemic of diphtheria a patient with a staphylococcus throat infection who had by mistake been placed in the diphtheria ward did not contract diphtheria. He also observed that in a number of diphtheria convalescents, in whose throats the bacilli were present, intercurrence of ordinary sore throats caused a disappearance of the Klebs-Loffler bacilli. Acting upon these observations he inoculated six cases by spraying the throats with a *Staphylococcus aureus* culture, obtained from a patient who had a pure staphylococcus sore throat. In all of these cases after two days cultures from the throats became negative, though in two of the cases they had been positive for two months. Henry Page of Manila (*Archives of Internal Medicine*, Vol. 7, No. 1, p. 16-23) reported a case treated successfully in this way. He concluded that as treatment of carriers had proved useless, local measures and antitoxin having no effect, and as pure cultures of *Staphylococcus pyogenes aureus* sprayed into the throat destroyed the Klebs-Löffler bacilli in from 48 to 72 hours, this treatment being harmless and effectual, they should be used in all carriers. S. R. Catlin and D. W. Day reported an epidemic of diphtheria in which the staphylococcus spray was successfuly used in eight cases, and concluded that the results with *Staphylococcus aureus* spray were such as to warrant its further use. Dr. Wiener said that a few weeks ago a case of diphtheria came under his care. He immediately injected 500 units of antitoxin and after four days all membrane disappeared and the child was practically well, but nine cultures were taken during the following three weeks, and all were positive, though application of silver solution and various sprays and gargles had been used. On December 11, 1911, three and one half weeks after the onset of the disease, a light 24-hour bouillon culture of staphylococcus pyogenes aureus was used three times a day as a spray. On December 12, the culture was positive and a spray with twice as heavy a culture was employed. On December 13, the throat culture, though still positive, showed fewer organisms. A heavy culture was used every three hours this day. On December 14 the culture was negative and pure staphylococcus showed on the slide. No further treatment was given and, on December 18, four days after the last spraying the culture showed a staphylococcus and a Gram-negative coccus, probably *Micrococcus catarrhalis;* plating out showed no bacilli. The culture used in this case was a laboratory culture of *Staphylococcus aureus* almost a year and a half old. At no time was there any local or constitutional disturbance in this case. Dr. L. K. Neff had used the spray in two very virulent cases, and the throat cultures became negative after four days' use of the bouillon spray. It would be presumptuous to draw conclusions from such a limited experience, but the possibilities of this procedure were so great that its was worth a thorough test. The *Staphylococcus pyogenes au eus* cultures in bouillon could be procured at any bacteriological laboratory without difficulty. A fresh live culture must be used daily.

The following papers were from the service of the New York Hospital:

Four Cases of Pernicious Anemia Treated by Repeated Small Injections of Defibrinated Blood.—Dr. JAMES C. GREENWAY made these reports. He said that Parum in 1863 stated the following: I. Related blood remained intact after transfusion and even made up for the loss of the original blood. II. Foreign blood was destroyed after transfusion and in addition produced an injurious effect. III. Blood lost nothing by defibrination. The danger of using it was dismissed because of less liability to intravascular clotting. Gussereau in 1871 attempted to control the severe symptoms by transfusion of blood but without success. This was the experience of many others until Quincke in 1877 obtained great success in one case (143,000 red blood cells) by intra-arterial transfusion of 85 c.c. of defibrinated blood. Success alternated with failure in the attempts of many; one of the notable successes was made by Ewald in 1895 after intravenous transfusion of 85 c.c. of defibrinated blood. Morawitz in 1907 reported good results from this transfusion in those cases in which arsenic was of no value. He first stated that the amount of blood used was not the main thing since the effect was produced, in his opinion, by the stimulation of the bone marrow and not by the physiological effect of adding to the amount of fluid. A. Weber reported in 1909 a series of cases in which small amounts of defibrinated blood were used and some improvement was noticed in every case. His conclusions were very guarded. His statement was that mere injections of small quantities of defibrinated blood alone might not produce marked improvement, but combined with the hygienic and dietetic care of a hospital, their efforts compared favorably with those cases upon which arsenic, or a large amount of blood was used. Since this paper there had been twelve or fourteen papers published on this same subject and the results reached were practically the same as Weber's. Technique: Under strict precautions, to guard against hemolysis, agglutination, the introduction of syphilitic blood or blood from one suffering from malaria, etc., 30 or 40 c.c. of blood were removed from the median basilic or cephalic vein of the donor; the blood was received into a sterile flask containing sterile garnet beads, or a cylinder supplied with a spiral wire. This was shaken or whipped, as the case might be, for from fifteen to twenty minutes, and was then filtered through four to five layers of fine meshed sterile gauze into sterile test tubes, one to contain sufficient for one injection. The others were stoppered with cotton and kept on ice for preservation. In injecting, care must be taken to have the blood warmed to 105° F. or thereabouts; when the vein was exposed, the injection should be made slowly and the usual precautions of having no bubbles in the syringe or needle. With regard to the ill effects after the injection of from 75 to 85 c.c. practically all of the cases reported showed marked anxiety, dyspnea, chills and elevation of temperature; but all of these symptoms disappeared after a few hours. Quincke reported instances of hemo-

globinuria and nephritis which were also of short duration. Morawitz had two cases followed by cyanosis and fever, and both ended favorably. He stated that he had not known of a fatal result. Hurter had one bad reaction after the injection of whole blood, probably because of an embolus, and one death. Defibrinated blood never gave in his hands such evil symptoms. In the four cases that Greenway reported, on one occasion only, there was experienced for a period of from one to two hours faintness, chilliness, pain in the legs, with flushing of the face. There was no temperature nor increase in respirations nor in the pulse rate. Similar symptoms, but of longer duration, had been reported in a leucemic case; this patient received only one or two injections. On one occasion a patient received the blood of a patient who had a blood pressure of 225. He had a passing headache with faintness and was all right in less than an hour after the injection was given. In another case there appeared a rise of temperature which was probably not associated with the injection; in this instance the infusions were stopped. In looking at the charts one could follow the course of the number of red blood cells and the percentage of hemoglobin. In one case the patient improved sufficiently to undergo the urgent necessity of having the uterus emptied. Unfortunately she got up a streptococcic septicemia and died. In the second case in which the onset of the disease quickly followed the extraction of a tooth there followed a severe hemorrhage lasting twelve hours, and this was followed by an infection of the gums which sloughed away in great masses. It was in this condition that she entered the hospital. Her decline was a rapid one, although the condition of her mouth was soon relieved. The course of the disease in this case was too rapidly fatal to give a fair chance for the treatment reported. The third case gave a prize result which, of course, can not be directly attributed to the defibrinated blood. In the fourth case the improvement was slow but continued steady and the results are still uncertain. In connection with this report charts were shown of the changes in the hemoglobin, red blood cells, and color indices which were practically coincident with the changes in the general condition. The results of any therapeutic procedure, in this particular disease especially must be very guarded, since it was notoriously subject to rapid changes for better or worse, and marvelous results have been reported practically in connection with all therapeutic measures, in one notable case where no therapeusis was attempted. The dangers of coincidence between improvement and any therapeutic procedure were great.

Dr. Lewis A. Conner said that the case reported was one that came into the hospital in extremis, apparently progressive and a fatal case of aplastic anemia. The outlook seemed as unfavorable as could be imagined. There was, however, a startling and progressive improvement under the treatment given, but he would not say positively that it was due to the injections of the defibrinated blood. They very often saw these improvements occur in pernicious anemia and it would be foolish for him to state that it was due to these injections. For some time this patient had been upon sodium cacodylate but without any appreciable change. In four cases in which the injections were used they were up and about the wards and entirely different individuals compared to what they were when they entered the hospital. They saw from year to year many cases of pernicious anemia, but they had never seen such a group of cases which showed such a marked improvement under this method, and he thought the method advocated was well worthy of a trial.

An Analysis of the Functional Tests for Cirrhosis of the Liver.—Dr. N. B. Foster said that for two years they had been working on the functional tests and particularly those that related to the hepatic function. One point that was studied was, whether or not the liver was capable of forming urobilin or not. In cases of cardiac compensation, where this organ was not much enlarged, the presence of urobilin was indicative of an enlarged and cirrhotic liver. Urobilin was also present in a large number of conditions in which there was a blood destruction; it was also present in many infectious diseases; it was also present in many miscellaneous diseases. His results in regard to cirrhosis of the liver showed that urobilin was present in about 05 per cent. of the cases. The presence of urobilin in the urine could be taken as indicative of the presence of cirrhosis of the liver, although it was present in many other cases. The urobilin reaction was determined by a very delicate test which Dr. Foster described. But it should be remembered that the presence of urobilin in the urine, although present in the urine in cases of cirrhosis of the liver, was not distinctive of that condition, because it appeared in so many other conditions. Much experimental work had been done which Dr. Foster described in detail.

Case of Myeloid Leukemia with a Low Leucocyte Count and Peculiar Febrile Relapses.—Dr. J. C. Roper reported this case. The spleen was enlarged so that it extended to the median line. The patient was admitted to the hospital with a temperature of from 104° to 106° F. The patient had suffered from severe pain. The Wassermann reaction was negative. The leucocyte count varied from 30,000 to 15,000 and finally reached the low number of 8,000. When the patient had no fever there was no leucocytosis. Ehrlich's salvarsan was given without harm to the patient. The blood count was normal so far as the red cells were concerned. After being in the hospital four months the patient died. The various glands diminished in size during the non-febrile periods and they also became less tender. Whether the spleen was movable or not he could not tell. The autopsy revealed a very large spleen, very large peribronchial and mesenteric lymph nodes, those in the region of the liver being especially enlarged. One of them measured 3 x 2 cm.

A Case of Myeloid Leukemia with Predominance of Eosinophile Cells.—Dr. R. G. Stillman reported this case. The patient, a waiter 27 years of age and a native of Spain, gave a family history that was negative and a personal history of lues which was doubtful. He was a pronounced sexual neurasthenic. He was admitted to the New York Hospital in March, 1911, complaining of indefinite pains over the entire body, weakness and a loss of normal color. Physical examination showed a rather under-sized man with swarthy skin and pale mucous membranes. The lymph nodes in the right posterior cervical, the right epitrochlear, and both inguinal regions were enlarged. The liver and spleen were also enlarged and there was distinct tenderness in the occipital region. While in the hospital he developed a sore throat with enlargement of the submaxillary glands which lasted only a few days. After a stay at the hospital of about a month he showed no improvement and went home. An *x*-ray examination of the chest and abdomen was negative. The Wassermann reaction reported after he left was positive. His urine consistently showed a trace of albumin and a few casts. Repeated examination of the stools failed to reveal ova or parasites. The point of interest in this case was the blood picture. The leucocyte count varied from 118,000 to 165,000 and eosinophiles from 85.8 per cent. to 91 per cent. A typical differential count was made at the time when the white cells numbered 105,000 was as follows: Polymorphonuclears 3.8 per cent., or 0,270; eosinophile polymorphonuclears, 69.8 per cent., or 115,170; eosinophile metamyelocytes, 19.4 or 32,010; eosinophile melocytes, 1.8 or 2,070, making altogether 91 per cent. or 150,150 eosinophiles; mesoblasts, .2 per cent. or 330; transitionals, .8 per cent. or 1,320; lymphocytes, 4.2 per cent. or 6,930. There

were 2 normoblasts per 100 pencocytes. These polynuclear eosinophiles were rather larger than those normally found in the blood and the granules were slightly smaller. Although smears were stained with a number of different stains the granules retained their distinctive eosinophile character. The neutrophiles were atypical. The relatively small number of myelocytes were all eosinophilic and differed in no way from those found in leucemic blood. Another unusual condition was the large number of metamyelocytes, which were without exception eosinophilic. The transitionals differed from the usual type in that the nucleus was large, irregular, and with ill-defined edges. The writer had been unable in the literature to find any instance where the eosinophiles had reached the high figure that they did in this case. Unfortunately they had been unable to find the patient and to see how the blood picture had changed. During a part of his stay in the hospital he was on a purin-free diet, and as usual in cases of pronounced leucocytosis the uric acid output was increased, being about 75 per cent. greater than the average. Although the eosinophile granules were said to contain phosphorus there was no evidence of it in the urine.

Tracings Showing the Influence of Cheyne-Stokes Breathing Upon Pulsus Alternans.—Dr. H. F. B. PARDEE read this paper and exhibited tracings. Those of the respirations were made with the usual spring pneumograph. This connected with a Marey tambour recorded inspiration as a downward stroke and expiration as an upward stroke. For the pulse tracings a modified Erlanger and Ushoff sphygmomanometer was used. It consisted of an inflatable rubber arm cuff, the interior of the cuff being connected with a fairly soft rubber bulb, a T or Y connection allowing air to be pumped into the system. About the outside of the soft rubber bulb was an airtight chamber with an opening to which connection was made with a Marey tambour by means of rubber tubing. The cuff was placed about the arm above the elbow in the usual way and the pressure raised so as to obliterate the radial pulse. If the pressure in the cuff was lowered slowly, at a point above systolic pressure varying with different pulses the lever of the tambour would begin to move synchronously with the impact of the brachial pulse upon the inflated cuff. As the pressure in the cuff was lowered the movement of the lever increased in amplitude to a maximum just above the diastolic pressure, after which it decreased. In order to facilitate better comparison of the individual beats the kymograph drum had been moved very slowly as could be seen by the time recorder. The first tracing shown was taken from a normal individual in which the slight variation in the amplitude synchronous with respiration could be easily seen in the first section and in succeeding sections at greater speeds it could be seen with increasing difficulty. The second tracing was from a man who entered New York Hospital on December 18, 1911, with general arteriosclerosis, aneurysm of the ascending arch of the aorta, aortic insufficiency and probably a poor myocardium, all thought to be due to syphilis. He had had first break in compensation two months previously, but had recovered and was complaining of weakness, dyspnea and some edema of the ankles. His pulse was 120 and jugular in force but not in rate, and his respirations were of the Cheyne-Stokes type. Jugular and radial tracings showed a normal heart action and a pulsus alternans. In another tracing taken the following day the Cheyne-Stokes character of the respiration was plainly shown. The brachial tracing showed beats of alternating size, due to the alternating greater and less force of succeeding pulse beats. During the periods of dyspnea the alternating character was much more marked than during the apnea periods. This increase was of gradual onset. This patient improved after three days and no longer showed the pulsus alternans. There were two other tracings from a man who entered the New York Hospital on November 8, 1911, with chronic nephritis, general arteriosclerosis, a history of lues and a much hypertrophied heart and moderately severe decompensation. On admission his heart showed frequent extra systoles. He made an uneventful recovery. His blood pressure rose during this time from 100 to 190 mm. of mercury and on December 15 his pulse was found to be of the alternans type proven by jugular tracings not to be extrasystoles. On December 17 his respirations were of the Cheyne-Stokes type at times and the following day continuously so. Another tracing showed the same features, a pulsus alternans coincident with Cheyne-Stokes respiration, in which the alternation gradually increased during the phase of augmentation and gradually decreased during the phase of decline. A few days later the patient again showed extrasystoles, which increased in frequency. Another tracing taken December 29 showed the pulsus alternans, with greater alternation during the dyspnea periods than during the apnea. Two explanations might be offered for these variations in the alternating character of the pulse occurring synchronously with the phases of the Cheyne-Stokes respiration. It might be a result of increased vagus activity of the respiratory and vasomotor centers during the dyspnea phase of the Cheyne-Stokes breathing. If this were so they should expect a slowing of the heart rate also unless the vagus stimulation was so slight as to effect only the function of contractility of the heart. Or it might be that during the dyspnea the blood was aspirated into the thorax by the respiratory movements, thus increasing the venous return and producing a better filling of the heart. The increased demand on the heart's power might be sufficient with a weakened myocardium to bring out a latent tendency to alternation. The alternation already present might tend to increase and to produce other signs of cardiac overstrain.

Remarks Upon Certain Accidental Murmurs in the Pulmonic Area.—Dr. L. A. CONNER read this paper in which he called attention to a certain type of these murmurs which he had failed to find mentioned in the literature on the subject. In the course of the examination of diseased hearts in the wards of hospitals he had gradually become aware of the fact that in many cases in which there was a very marked accentuation of the pulmonic second sound, this accentuated sound was preceded by a short rough and usually loud systolic murmur heard best in the second left space, or wherever the accentuated sound was best heard. As mitral stenosis was the condition in which one saw the most exquisite example of accentuation of the pulmonic second sound, so it had been in this condition of mitral stenosis that he had usually found this rough systolic murmur. In mitral stenosis, as was well known, it was common not only to hear the greatly accentuated sound over the pulmonary artery but also actually to feel distinctly the shock of the closure of the pulmonic semilunar valves. In the same way it was often possible, not only to hear the rough murmur preceding the ringing second sound, but also to feel over the pulmonary artery the systolic thrill corresponding to the murmur. While mitral stenosis was the condition in which he had usually heard this murmur he had occasionally heard it in other conditions, but so far as he could recall never without its being associated with great accentuation of the pulmonic sound. The most striking instance of this that he had seen was in a young man comatose from acute uremia who, in addition to a greatly accentuated second pulmonic sound, had an extremely rough and loud systolic murmur heard best in the second left space and transmitted some distance upward and toward the left. With the murmur there was a pronounced coarse thrill over the same region. The murmur was so loud as to arouse the suspicion of a pericarditis. The autopsy showed an hypertrophied and dilated heart but absolutely nothing to explain the extraor-

dinary murmur and thrill. The features of this murmur were that it was rough and loud, while most accidental murmurs were described as soft and blowing, that it was associated with unusual accentuation of the pulmonic second sound which it immediately preceded and that it had been heard chiefly in mitral stenosis. As to the mode of origin of these murmurs there seemed to be little that was satisfactory to offer. The most satisfactory hypothesis seemed to be that of Sahli, who said that when they considered the anatomical condition within the heart, the roughened irregular walls, the narrow orifices, etc., the surprising thing was not that the movement of the blood stream through it should occasionally produce a murmur but that the blood should be able to flow through it without producing a murmur. He thought the reason for this was that the velocity of the blood current through the heart was ordinarily not sufficiently great to produce such a murmur, but that when the velocity was sufficiently increased such murmurs arose. In certain conditions in which such functional murmurs were especially common the heart seemed to contract with unusual suddenness and it seemed reasonable to suppose that in such conditions the velocity of the blood current might be considerably increased. In mitral stenosis one of the most striking and characteristic features was the sudden, sharp systolic contraction and moreover the right ventricle must often contain an abnormally large quantity of blood, so that the velocity of the blood as it passed into the narrow pulmonic orifice must often be very considerably greater than normal. It therefore, seemed not unreasonable in such cases to expect just such a murmur as they not infrequently heard. Whether this explanation was correct or not the fact remained that these murmurs were not due to any valvular or other organic disease.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS

January 2, 1912

ANATOMY.

1. Describe the radius, including the attachments of muscles and ligaments.
2. Describe the bones of the carpus.
3. Describe the ankle joint.
4. Describe the shoulder joint with special reference to its surgical anatomy.
5. Give the origin, insertion, and nerve supply of the following muscles: sartorius, gastrocnemius, serratus magnus, quadratus lumborum, flexor profundus digitorum.
6. Name the triangles of the neck and the important structures contained in each.
7. What muscles supinate the forearm? Give the origin and insertion of each.
8. Describe the large intestine, including relations.
9. What muscles derive their nerve supply from the anterior primary divisions of the fifth and sixth cervical nerves?
10. Give a brief description of the ducts that carry bile from the liver to the intestine.

PHYSIOLOGY.

1. In what part of the digestive tract is the pancreatic juice mixed with the food? What is its reaction? Name its ferment and what action does it have on food?
2. Give the function of (*a*) the cerebrum, (*b*) the cerebellum, (*c*) the external ear, (*d*) the mouth, (*e*) the spleen.
3. Give in detail the function and action of the liver and gall-bladder.
4. Describe the skin and mention three of its functions.
5. Name and describe the component parts of blood and by what organs it is distributed through the body.
6. Name five ductless glands. Tell where each is located and name the secretions.
7. Name the three layers of the blastoderm and mention what parts of the adult are developed from each.
8. What does the sympathetic nervous system supply?
9. What five nerve centers are located in the lumbar enlargement of the spinal cord?
10. Name three nerves that supply motor impulses to the eye.

CHEMISTRY.

1. What is an alkaloid? Name three alkaloids used as medicines.
2. Name three of the halogen group. What are their chemical characteristics?
3. Enumerate the chemical constituents of normal urine.
4. Give the chemical formulæ of three common salts.
5. What do you understand by the term "chemical incompatibility"?
6. What is an acid salt?
7. What is neutral salt? Give two examples.
8. What is an alkaline salt?
9. What are the principal chemical constituents of normal gastric juice?
10. What is indican, and what is its significance when found in considerable quantity in the urine?

TOXICOLOGY.

1. Give symptoms of poisoning by sulphate of copper.
2. Give treatment of poisoning by sulphate of copper.
3. What are the symptoms of poisoning by tartar emetic?
4. How would you treat a case of poisoning by tartar emetic?
5. Give post-mortem appearance of poisoning by tartar emetic.
6. Give symptoms of poisoning by aqua fortis.
7. Give treatment of poisoning by aqua fortis.
8. What are the post-mortem appearances of poisoning by aqua fortis?
9. What are the symptoms of poisoning by aconite?
10. Give treatment of poisoning by aconite.

PATHOLOGY.

1. Classify tumors.
2. Discuss the gross pathology of congenital syphilis.
3. Describe the *Spirochæta pallida*.
4. What changes occur in the female genital apparatus from infection by the gonococcus?
5. Describe the Charcot joint.
6. What changes occur in the myocardium secondary to coronary disease.
7. How would you distinguish the tubercle bacillus from the smegma bacillus?
8. What changes occur when a peripheral nerve is cut?
9. Give the pathology of acute osteomyelitis.
10. Describe a peptic ulcer.

SYMPTOMATOLOGY.

1. What are the physical signs of lobar pneumonia?
2. What are the physical signs of bronchopneumonia?
3. What are the symptoms of diabetes mellitus?
4. What are the symptoms of rickets?
5. What are the symptoms of appendicitis, and what is the order of their appearance?
6. What are the physical signs of pericarditis?
7. What are the symptoms of arteriosclerosis?
8. Describe the blood picture in pernicious anemia.
9. What are the symptoms of Hodgkin's disease?
10. Name the various forms of nephritis and give the urinary findings in each.

OBSTETRICS.

1. Name indications for and give technique of the use of high forceps.
2. Mention the varieties of hemorrhage that may affect a parturient woman, and how would you treat them?
3. How would you diagnose the position of the child (outline form)?
4. What is placenta prævia, and how would you manage a case?
5. Give the (bony) measurements of the pelvis.
6. Give the average duration of labor in primiparæ and multiparæ.
7. Name the female organs of generation complete.
8. Mention some developmental abnormalities of the uterus.
9. Describe the ovum at the time of its discharge from the ovary.
10. Describe the migration of the ovum.

SURGERY.

1. Give the causes, symptoms, and diagnosis of fat-embolism.
2. What are the symptoms and complications of prostatic hypertrophy?
3. What are the causes and how would you determine the source of pus in the urine?

4. How should patients be prepared for the administration of anesthetics?

5. What complications may follow fractured ribs?

6. Give the varieties of hemorrhage and the methods of controlling it.

7. Give the causes of gangrene.

8. Describe Pott's fracture, the deformity that may follow, and the precautions to be taken in treatment.

9. Give the symptoms and prognosis of tuberculous peritonitis.

10. Describe the symptoms of a well developed tuberculous arthritis of the hip.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

COLORADO STATE BOARD OF MEDICAL EXAMINERS.

January 2, 1912.

ANATOMY.

1. See Cunningham's "Anatomy" (1909), pages 198 and 279 to 284; or Gray's "Anatomy" (1910), pages 190, and 306 to 315.

2. See Cunningham's "Anatomy" (1909), page 201; or Gray's "Anatomy" (1910), page 195.

3. See Cunningham's "Anatomy" (1909), page 306; or Gray's "Anatomy" (1910), page 342.

4. See Cunningham's "Anatomy" (1909), pages 276 and 1291 or Gray's "Anatomy" (1910), pages 301 and 304.

5. SARTORIUS. *Origin:* Anterior superior spine of ilium. *Insertion:* Upper internal portion of shaft of tibia. *Nerve supply:* Anterior crural.

GASTROCNEMIUS. *Origin:* Condyles of the femur. *Insertion:* Os calcis (by tendo Achillis). *Nerve supply:* Internal popliteal.

SERRATUS MAGNUS. *Origin:* Eight upper ribs. *Insertion:* Inner margin of dorsal border of scapula. *Nerve supply:* Posterior thoracic.

Quadratus lumborum. Origin: Crest of ilium, transverse processes of lower three lumbar vertebræ. *Insertion:* Last rib, transverse processes of upper three lumbar vertebræ. *Nerve supply:* Twelfth thoracic and upper lumbar.

Flexor profundus digitorum. Origin: Shaft of ulna. *Insertion:* Last phalanges of fingers (by four tendons). *Nerve supply:* Ulnar, and anterior interosseous.

6. See Cunningham's "Anatomy" (1909), page 1249; or Gray's "Anatomy" (1910), page 605.

7. *Muscles that supinate the forearm:* Supinator longus, biceps, brachialis anticus, supinator brevis, extensors of thumb.

SUPINATOR LONGUS. *Origin:* External condyloid ridge of humerus. *Insertion:* Styloid process of radius.

BICEPS. *Origin:* Glenoid cavity and coracoid process of scapula. *Insertion:* Tuberosity of radius.

BRACHIALIS ANTICUS. *Origin:* Lower half of anterior surface of shaft of humerus. *Insertion:* Coracoid process of ulna.

SUPINATOR BREVIS. *Origin:* External condyle of humerus and oblique line of ulna. *Insertion:* Neck of radius and its bicipital tuberosity.

8. See Cunningham's "Anatomy" (1909), page 1076; or Gray's "Anatomy" (1910), page 1296.

9. The supra spinatus, infraspinatus, subscapularis, teres major, teres minor, and deltoid muscles derive their nerve supply from the fifth and sixth cervical nerves.

10. See Cunningham's "Anatomy" (1909), pages 1118 and 1120; or Gray's "Anatomy" (1910), page 1333.

PHYSIOLOGY.

1. The *pancreatic juice* is mixed with the food, in the duodenum. The *reaction* is alkaline. The ferments are: *Trypsin*, which changes proteids into proteoses and peptones; and afterward decomposes them into leucin and tyrosin; *Amylopsin*, which changes starches into maltose and dextrose; *Steapsin*, which emulsifies and saponifies fats.

2. *Function of the cerebrum:* It receives all the afferent impulses which enter into consciousness; the sensation of heat, cold, pain, sight, hearing, smell, taste, hunger, thirst, all arise in the cerebrum; movement is also originated in the cerebrum.

Function of the cerebellum: Coordination of muscular movements, and maintenance of equilibrium.

Function of external ear: The auricle collects the sound waves and transmits them through the external auditory meatus to the external auditory canal, and these sound waves impinge upon the membrana tympani.

Function of the mouth: Prehension and mastication of food, its insalivation and deglutition, and beginning of the digestion of starches.

Function of the spleen: This is not definitely settled; the following theories have been held: (1) It is a source of production of the white blood corpuscles; (2) it is a source of production of the red blod corpuscles during fetal life; (3) it is a place where the red blood corpuscles are destroyed; (4) uric acid is produced in the spleen; (5) an enzyme is produced in the spleen and is carried by the blood to the pancreas, where it converts the trypsinogen into trypsin.

3. The *functions of the liver* are: (1) the secretion of bile; (2) the formation and storage of glycogen; (3) the formation of urea and uric acid; (4) the manufacture of heat; (5) the formation of creatinine; (6) the production of antithrombin; (7) the conversion of poisonous and harmful into inert material; (8) it is also a reservoir for blood on its way to the heart.

The *function of the gall-bladder:* (1) To store the bile secreted in the liver; (2) to expel the bile into the duodenum.

4. See Cunningham's "Anatomy" (1909), page 772; or Gray's "Anatomy" (1910), page 1151.

Three functions of the skin: (1) Protection; (2) it is a specialized sense organ, for touch; (3) it helps in regulating the temperature of the body.

5. The *blood* is fluid, somewhat viscid, red, specific gravity from 1055 to 1062, alkaline reaction, saltish taste, characteristic odor, variable temperature (average about 100° F.). The *constituents* are plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteins, fat, and inorganic salts). The *white corpuscles* consist of water and solids (protein, leuconuclein, lecithin, histon, etc.). The *red cells* are biconcave discs, about 1-3200 of an inch in diameter; they are nonnucleated, and there are about 4,500,000 or 5,000,000 of them in each cubic millimeter of blood. They are elastic and soft, and their shape is changed by pressure, but is promptly regained on the removal of the pressure. Their color is yellowish. They contain hemoglobin. They carry oxygen from the lungs to the tissues. The white blood cells are spheroidal masses, varying in size, having no cell wall, and containing one or more nuclei; there are about 7,000 to 10,000 of them in each cubic millimeter of blood. They differ much in appearance, and are divided into (1) small mononuclear leucocytes, or lymphocytes; (2) large mononuclear; (3) transitional; (4) polynuclear, or polymorphonuclear, or neutrophile, and (5) eosinophile. They are all more or less granular, particularly the last two varieties named. They are probably formed in the spleen, lymphatic glands, and lymphoid tissues. Their fate is uncertain; it has been asserted that they are converted into red blood cells; they play a part in the formation of fibrin ferment; they are sometimes converted into pus cells. Their functions are (1) to serve as a protection to the body from the incursions of pathogenic microorganisms; (2) they take some part in the process of the coagulation of the blood; (3) they aid in the absorption of fats and peptones from the intestine, and (5) they help to maintain the proper proteid content of the blood plasma.

There are also *platelets*, which are very small, colorless, irregular shaped bodies; they are about one-fourth the diameter of a red corpuscle. The function is not determined; it is possible that they take some part in the coagulation of the blood. In number they vary from about 200,000 to more than 500,000 in each cubic millimeter of blood. *Plasma* conveys nutriment to the tissue; it holds in solution the carbon dioxide and water which it receives from the tissues, and takes them to be eliminated by the lungs, kidneys, and skin; it also holds in solution urea and other nitrogenous substances that are taken to and excreted by the liver or kidneys. *Arterial blood* is bright red in color, contains more oxygen, less carbon dioxide, more water, and is slightly warmer; *venous blood* is purple in color, contains less oxygen, more carbon dioxide, less water, and is slightly cooler (except in the hepatic vein). It is distributed through the body by the heart, arteries, capillaries, and veins. See Cunningham's "Anatomy" (1909), pages 780, etc.; or Gray's "Anatomy" (1910), pages 549, 575, and 707.

6. *Five ductless glands:* Spleen, thyroid, thymus, suprarenals, and parathyroids.

For *location*, see Cunningham's "Anatomy" (1909), pages 1210, etc.; or Gray's "Anatomy" (1910), pages 1437, etc.

For *function of spleen*, see above, QUESTION 2.

The function of the thyroid is not definitely settled; (1) it has some trophic function, regulating oxidation in the body, and it is supposed to have also a special influence

on the vasomotor nerves, the skin, the bones, and on the sexual functions; (2) it is supposed to antagonize toxic substances, and (3) it produces an internal secretion.

The *function of the thymus* is not settled; it is said: (1) To be a blood-forming organ; (2) to have influence on growth and nutrition; (3) in hibernating animals it is supposed to store up materials which can be utilized during the period of inactivity.

The *function of the suprarenals* is not definitely settled; they produce an internal secretion which is probably necessary to life; it is supposed that they are able to destroy or remove some toxic substance produced elsewhere in the body.

The function of the *other ductless* glands is unknown. They all, or nearly all, furnish an internal secretion.

7. *The three layers of the blastoderm* are: The epiblast, mesoblast, and hypoblast.

From *the epiblast* are derived: The skin, and its appendages (hair, nails), and glands (including the mammary glands); the nervous system (brain, spinal cord, ganglia and nerves); the epithelial parts of the organs of special sense.

From *the mesoblast* are derived: The skeleton; connective tissues; muscles and bones; heart, blood-vessels, lymphatics, and spleen; the urinary and generative organs. From *the hypoblast* are derived: The epithelial lining of the alimentary canal and its glands; the epithelial lining of the respiratory tract, Eustachian tube, thyroid and thymus.

8. The *functions* of the sympathetic nervous system: "It may safely be said that sympathetic system has, to a great extent, a controlling influence over the secretion of most of the glands, the lacrymal, the salivary, the sweat glands, the glands of the stomach and intestines, the liver, the kidney, etc.; that it presides over the circulation by regulating the caliber of the blood-vessels and the action of the heart; that it influences respiration; and, finally, that all involuntary muscles, those of the digestive apparatus, of the genitourinary system, of the hair follicles (pilomotor-nerves), are under its control to such extent that, for instance, in certain mammalians the bladder still continues to fulfill its function for weeks after all the cerebrospinal motor nerves leading to it have been severed. In short, we find that all vegetative life of the organism is, to a greater or lesser extent, under the control of the sympathetic system. Therefore it may properly be called the vegetative nerve system *par excellence*."—(*Reference Handbook of the Medical Sciences.*)

9. *Nerve centers located in the lumbar enlargement of the spinal cord are:* Centers for urination, defecation, parturition, erection of the penis, and ejaculation of seminal fluid.

10. *Three nerves that supply motor impulses to the eye:* (1) Motor oculi, or 3rd cranial; (2) trochlear, or 4th cranial; and (3) abducens, or 6th cranial.

CHEMISTRY.

1. An *alkaloid* is a basic, nitrogenous, organic substance, of alkaline reaction, and capable of combining with acids to form salts in the same way that ammonia does.

Three alkaloids used in medicine: Strychnine, quinine, and morphine.

2. *Three of the halgen group:* Fluorine, chlorine, and bromine.

They are all univalent elements, they all unite with hydrogen to form hydracids; their hydroxides (but fluorine does not form one) are monobasic acids; they are all extremely irritant; and they possess bleaching and disinfecting properties.

3. *Chemical constituents of normal urine:* Water; urea, uric acid, hippuric acid, creatine, creatinine, xanthine, hypoxanthine; chlorides, sulphates, and phosphates (of sodium, potassium, magnesium, and calcium), ammonia.

4. Sodium chloride, NaCl; silver nitrate, $AgNO_3$; and borax, $Na_2B_4O_7$.

5. *Chemical incompatibility* is that form of incompatibility in which chemical interaction (generally not intended by the prescriber) results; the ingredients undergo a chemical change, and a new chemical compound results.

6. An *acid salt* is one in which only part of the replaceable hydrogen of the acid has been replaced by a metal (or its equivalent), as $KHSO_4$.

7. A *neutral salt* is one in which all of the replaceable hydrogen of the acid has been replaced by a metal (or its equivalent), as K_2SO_4, $Ca_3(PO_4)_2$.

8. An *alkaline salt* is a basic salt, that is a compound of the normal salt with a hydroxide, or oxide of the metal.

9. *The principal chemical constituents of normal gastric juice* are: Water; pepsin; hydrochloric acid; chlorides (of sodium, potassium, calcium, and ammonium); and phosphates (of calcium, magnesium, and iron).

10. *Indican* is indoxyl potassium sulphate. When found in considerable quantity in the urine it may denote: Putrefactive changes in the body, or hypochlorhydria, or gastric ulcer or diminished peristalsis in the small intestine.

TOXICOLOGY.

1 and 2. COPPER SULPHATE (BLUE VITRIOL). *Symptoms:* "A 'coppery' taste, soon followed by nausea and vomiting, which becomes violent and persistent (the vomited matters being colored blue or green, according to the amount taken and the contents of the stomach), severe pain in the stomach and bowels, with flatulence and eructations. There is generally some diarrhœa, the stools black or reddish brown, and streaked with blood. The pulse is small, sharp, rapid, and sometimes irregular, the skin cold and clammy, thirst burning and persistent, great prostration, dyspnœa, urine scanty and voided with difficulty and pain. In the later stages neurotic symptoms appear, vertigo, cramps, tetanic spasms, paralysis, coma and collapse. In some cases there is salivation, and, if the case continues, jaundice appears, thus distinguishing this from mercurial or arsenical poisoning."

Treatment: "Encourage vomiting with copious draughts of warm water, or wash out stomach with solution of potassium ferrocyanide. Give albumin (eggs), milk, diluent drinks, calcined magnesia, or other alkalies, or soap. It is not best to give oils."—(Riley's *Toxicology.*)

3, 4, and 5. TARTAR EMETIC. *Symptoms:* "These are seldom delayed more than half an hour. Nausea, violent and continual vomiting, burning pain in stomach and bowels, with an acrid, burning sensation in the throat, are usually the first symptoms. Then purging, intense thirst, feeble, rapid pulse, cramps in legs, and general lowering of the temperature, with great prostration, follow. The coldness extends even to the internal organs. The bowels become tympanitic. The spinal centers are greatly depressed. The urine is generally increased, but sometimes diminished or suppressed, and may be bloody and passed with difficulty and pain. Delirium and convulsions may precede death, or the patient may sink into coma, or die from exhaustion. The progress of the case often resembles arsenical poisoning so closely that it is difficult to decide which it is without chemical analysis. Generally, however, the persistent nausea and vomiting will distinguish between them. Sometimes neither vomiting nor purging is seen. In such cases the patient is apt to collapse, with cold sweat, feeble respiration, cyanosis, delirium, irregular pulse, and lapse into unconsciousness and die in convulsions."

Treatment: "Wash out the stomach or assist vomiting by abundant warm demulcent drinks. Then give tannin in some form. As the poison is quite rapidly absorbed, promptness is important. It is well in washing out the stomach to use some form of tannin solution, as tea, infusion of oak bark, etc., if available. Borax in milk (5 per cent. solution) has been used with much apparent success. Then sustain the heart with strychnine hypodermically, digitalis or strophanthus. If nausea is persistent opiates may be necessary."

Post Mortem Appearances.—"The mucous membranes of the throat, stomach and bowels are usually red, softened, and show general signs of severe irritation or even inflammation. They (especially those of the stomach), are apt to be covered with small extravasations of blood and occasionally pustular eruptions. The mucous membrane of the bowels is frequently covered with a dark yellowish, viscid secretion. The brain and lungs are generally congested. In chronic cases the large intestine is also inflamed and the liver enlarged and softened."—(Riley's *Toxicology.*)

6, 7 and 8. AQUA FORTIS. *Symptoms:* Sudden and acute burning pain in epigastrium and extending from mouth to stomach; violent and distressing vomiting of acid and dark material. Eschars where the acid has come in contact with skin, lips or tongue; these are first white, then yellow or brown.

Treatment: Magnesia suspended in water, or a strong solution of soap. Do *not* use the stomach tube.

Post mortem appearances: "The mucous membrane of the mouth and throat is yellow. The stomach is distended with gas, if not perforated, and patches of yellow, brown or green are seen on its internal surface. Perforation is not common. The mucous membrane of the intestines is frequently grayish white or bluish. The kidneys are inflamed and swollen and the liver degenerated in protracted cases. Evidences of inflammation of the lungs are frequently found."—(Riley.)

9 and 10. "*The symptoms of poisoning by aconite* usually manifest themselves within a few minutes; sometimes are delayed for an hour. There is numbness and tingling, first of the mouth and fauces, later becoming general. There is a sense of dryness and of constriction in the throat.

Persistent vomiting usually occurs, but is absent in some cases. There is diminished sensibility, with numbness, great muscular feebleness, giddiness, loss of speech, irregularity and failure of the heart's action. Death may result from shock if a large dose of the alkaloid be taken, but more usually it is by syncope.

"The *treatment* should be directed to the removal of the unabsorbed poison by the stomach tube, and washing out of the stomach with infusion of tea holding powdered charcoal in suspension. Stimulants should be freely administered." (Witthaus' *Essentials of Chemistry.*)

PATHOLOGY.

1. A *tumor* is a pathological new growth which tends to persist independently of the structures in which it lies, and which performs no physiological function.

Tumors are classified as follows:

I. Those derived from mesoblast:
   (*a*) *Benign:* Lipoma, fibroma, chondroma, osteoma, myxoma, myoma, neuroma, glioma, angioma, lymphangioma.
   (*b*) *Malignant:* Sarcoma.
II. Those derived from epiblast or hypoblast:
   (*a*) *Benign.* Adenoma, papilloma.
   (*b*) *Malignant:* Carcinoma.
III. Cystic tumors.
IV. Teratomata.

2. See Rose and Carless' "Surgery" (1911), page 160; or Da Costa's "Surgery" (1911), page 337; or French's "Practice of Medicine" (1910), page 428; or Osler's "Practice of Medicine" (1909), pages 269, 273, and 274.

3. The *Spirochæta pallida* is a slender spirillum, with regular turns, the curves varying in number from three or four to twelve or even twenty; it is about 4 to 20 mikrons long, actively motile, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur. It is the microorganism found in syphilis.

	ACUTE NEPHRITIS.	CHRONIC NEPHRITIS.		
		Chronic parenchymatous nephritis; large white kidney.	Secondary contracted kidney; small white kidney.	Chronic interstitial nephritis; primary contracted or small red kidney; cirrhotic or granular kidney.
URINE. *Quantity.*	Scanty.	Rather less than normal...	Not less than normal; usually increased.	Very abundant.
Color.	Turbid, pale red or smoky to deep red.	Turbid, resembling meat infusion.	Fairly clear.....	*Clear*, pale.
Specific Gravity.	High....	Somewhat raised, may be normal.	A little below normal.....	Low.
Blood.	Abundant.....	Commonly present.....	In small quantity.....	Usually *absent.*
Albumin.	Abundant.....	Abundant	In moderate quantity.....	In very small quantity; may be absent for some time.
Sediment.	Abundant. White and red corpuscles; blood casts, epithelial and granular casts; urates.	Abundant. White and red corpuscles; numerous casts, especially *fatty*. .	In moderate quantity. Casts fairly numerous, granular and hyaline chiefly.	Very scanty. Casts few, chiefly hyaline.
Salts and Urea.	Marked diminution of urea, chlorides, and phosphates.	Diminution of urea, etc.....	Marked diminution of urea, etc.	Marked diminution of urea, etc.

(From Hughes' *Practice of Medicine.*)

7. The *smegma bacillus* is decolorized by a dilute mineral acid, also by heat and alcohol; the *tubercle bacillus* is not decolorized by either of these.

8. "When a nerve is divided the first result is a loss of its function. Inasmuch as each nerve-fiber develops from a cell which later nourishes it, if the connection between the two is severed the nerve-fiber undergoes Wallerian degeneration, and in the case of a nerve which is made up of nerve-fibers the whole nerve undergoes this change. This degeneration consists, in the case of medullated nerves, in the death of the axis-cylinder, the breaking up of the medullary sheath into drops of myelin, which are later absorbed, and the multiplication of the nuclei of the primitive sheath. In non-medullated nerves the only result is the death of the axis-cylinder. Degeneration begins very soon after the section—within a day or two—and throughout the entire severed portion of the nerve at the same time. Thus the course of a nerve, or a collection of nerves, may be traced throughout its entire extent. These changes are believed to be due to the severance of the nerve from its trophic center. If an anterior root of a spinal nerve is divided, the distal end, being separated from the gray matter of the cord which is its center of nutrition, undergoes degeneration, while the end which remains connected with the cord retains its integrity. If a posterior root is divided between the cord and the ganglion, the degeneration takes place between the cord and the ganglion; while if divided below the ganglion, the degeneration takes place in that portion separated from the ganglion, showing that the ganglion is the nutritive center for the posterior root." (Raymond's *Physiology.*)

SURGERY.

1. *Fat embolism:* "After various injuries and operations, but especially such as implicate the marrow of long bones—for example, comminuted fractures, osteotomies, resections of joints, or the forcible correction of deformities—fluid fat may enter the circulation in variable quantity. In the vast majority of cases no ill effects follow, but when the quantity is large or when the absorption is long continued certain symptoms ensue, either immediately, or more frequently not for two or three days. These are mostly referable to the lungs and brain.

"In the lung the fat collects in the minute blood-vessels and produces venous congestion and edema, and sometimes pneumonia. Dyspnea, with cyanosis, a persistent cough and frothy or blood-stained sputum, a feeble pulse and low temperature, are the chief symptoms.

"When the fat lodges in the capillaries of the brain, the pulse becomes small, rapid, and irregular, delirium followed by coma ensues, and the condition is usually rapidly fatal.

"Fat is usually to be detected in the urine, even in mild cases." (Thomson and Miles' *Surgery.*)

And see Da Costa's "Surgery" (1911), page 205.

2. See Rose and Carless' "Surgery" (1911), pages 1248 and 1251; or Da Costa's "Surgery" (1911), page 1374.

3. *Pus in the urine.* "The presence of pus in the urine is termed *pyuria* and usually indicates suppuration along the genitourinary tract. Its source may be detected to a great extent by the time of its appearance (as with blood) in the urine. When present in the early part of micturition the urethra is usually diseased, if at the end and in alkaline urine the trouble is in the bladder, but if it is freely admixed with an acid or neutral urine, the probabilities are that the kidneys are at fault. The addition of an equal quantity of a solution of potassium hydroxid to urine containing pus gives rise to the formation of a viscid gelatinous mass. The microscope may also be employed to detect pus."

(Hughes' *Practice of Medicine.*)

The Pathogenesis of Icterus.—E. Leuret and H. Gauvenet believe that the true question with regard to this subject is whether there are two different kinds of jaundice, one due to resorption into the blood of hepatic pigments and the other due to retention of pigments in the blood elaborated elsewhere than in the liver. The authors have devised a method for the study of icterus for which they claim some originality. They have compared with the aid of a color scale the blood serum, urine, and feces of icteric patients with reference to this pigmentary content. They conclude that all icterus by hemolysis is acholuric and all acholuric icterus is the result of hemolysis. Reciprocally choluric icterus is not hemolytic and is caused by a retention of pigments elaborated by the liver. The authors note the importance of the elimination of bile by the intestine. They have shown that there is a variety of icterus resulting from the formation by hemolysis of pigments which differ from bilirubin elaborated by the liver cells. This icterus is acholuric on account of the quality of the pigments, which are not eliminated by the urine. Other types of icterus arise from the retention of bile derived from the liver cells.—*Gazette Hebdomadaire des Sciences Médicales.*

Medical Items.

The Suprarenal Capsules in Erysipelas.—Lesne, Gérard, and Françon cite the histories of seven cases of erysipelas to show that suprarenal insufficiency is present with fatal results in some cases. A résumé of these cases shows that this condition of insufficiency is present after convalescence has been established. The general condition becomes worse, with manifest asthenia and lowered arterial tension, and death rapidly ensues. The cardiac dullness is found to be increased; the liver is increased in volume; there may be vomiting or diarrhea, and pronounced dyspnea. The condition is analgous to what occurs in severe cases of diphtheria. The hypotension is due to suprarenal insufficiency, the tone of the blood-vessels being no longer maintained. The end occurs with cardiac collapse. At autopsy the following changes are found in the suprarenal capsules: these are infiltration with uninuclear leucocytes; microscopic hemorrhages in the reticulum of the gland, with a dissociation of the cellular masses; there is an almost complete destruction of the medullary layer with cellular pycnosis.—*La Presse Medicale.*

Intratracheal Insufflation After Meltzer.—R. Falcone has employed a modification of Meltzer's method of intratracheal insufflation of oxygen and other gases. This apparatus is designed to produce artificially the natural rhythm of respiration. Introducing a tube through a tracheotomy wound down to the bifurcation of the trachea, and pumping in air at a certain rapidity and pressure, there is caused an interchange of gases in the pulmonary blood stream with the effect of artificial respiration without movements of the chest. This method may be utilized in cases of accident during narcosis, in cases of sudden death from asphyxia, and in the administration of anesthetics. It is a valuable resource in rapid operations on the thorax, but should be reserved for urgent cases.—*La Riforma Medica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended March 15, 1912:

THE GENERAL PRACTITIONER IN THE DEVELOPMENT OF APPENDICITIS MANAGEMENT.*

By SIMON BARUCH, M.D.,

NEW YORK.

"IT were bringing owls to Athens" to say aught about appendicitis before a Brooklyn audience, for right here has been done yeoman work in appendix surgery. Your invitation to discuss this subject is accepted because in the glamour of surgical achievement the humble but not less important share of the general practitioner has been lost sight of. Inasmuch as the family physician, a class to which I formerly belonged, is now relegated to the position of distributing agent, you may not regard me as wanting in modesty when I raise a feeble voice in advocacy of our kind. Only those who were in active practice during the seventies of the last century are in a position to appreciate the enormous gain which the evolution from the medical to the surgical view of appendicitis has bestowed upon suffering humanity. Many cases of "idiopathic peritonitis" were encountered and treated with poultices, leeching blisters, morphine, etc. The patients frequently succumbed as is shown in the following outline histories. During the early eighties of the last century I find recorded in my note book seven severe cases of perityphlitis, a disease which had but recently been recognized as a pathological entity. Four of these patients recovered and three died. The first fatal case was in a young man seventeen years old who limped into my office because of pain in the hip. His temperature was 102° F. I ordered him to bed and after a careful examination the diagnosis of acute perityphlitis was made. Dr. Francis Delafield saw him in consultation; he succumbed on the following day with all those manifestations which are now known as the result of perforation.

The second case occurred on June 7, 1883. G., a fine boy of eleven, complained of pain over the anterior spinous process on the right side; temperature 101°, pulse 120; taken sick on previous day, no tenderness in right iliac region until following day. Dr. Alfred Loomis was called in. Diagnosis: Perforating typhlitis; operation proposed by Dr. Leonard Weber five hours before death was not accepted by Dr. Loomis and myself. Patient died in forty-eight hours.

The third fatal case was in S. W., a boy of ten. He had vomited at stool on the previous night. Pulse 130, temperature 101.5°; intense pain on pressure over right iliac region, knees elevated for relief; turpentine enema and morphine made him comfortable. On following morning there was general peritonitis; temperature 102°, pulse 135. I urged immediate consultation which was delayed on account of inconvenience to the family until 8 P.M. Patient was comfortable and asked for food an hour before consultation with Dr. A. Jacobi. When we entered the sick room the patient was in collapse; he died three hours later with vomiting and great abdominal distention. I was so shocked by this sad case that I reviewed all the recent cases, entered them in my note book, and wrote the following:

"March 30, 1884. Conclusions from these cases are as follows: Diagnosis should be established with sufficient positiveness that perforation is threatening, laparatomy would be indicated because such cases are invariably fatal in my experience. But here is the difficulty. Is it advisable to open the peritoneum when local or perhaps diffuse peritonitis is evident? My three fatal cases would indicate an affirmative answer. The disease goes rapidly to a fatal issue; the usual treatment is unavailing. Another point presenting itself is the utter inutility of feeding the patient. Here we have a traumatic inflammation whose course is brief and which does not kill by asthenia. If vomiting threatens food should be withheld entirely and drink given in very small quantities. *The case should be treated as an ovariotomist treats his cases.* Dr. Jacobi makes a distinction between perityphlitis and paratyphlitis which has certain advantages, the latter being curable even if it forms an abscess, the former being mostly fatal." This is an abbreviated copy from my notebook.

Just at this point may be mentioned the remarkable fact referred to in Dr. Kelly's great work that "Dr. Samuel Fenwick, physician to the London Hospital, wrote in 1884 (Lecture, *London Lancet*, page 988): 'It seems to me it would be much better if one could cut down directly upon the appendix as soon as the diagnosis was tolerably certain, tie it above the seat of perforation, and remove any material that might be the cause of irritation.' Thus another general practitioner reached a similar conclusion to mine."

Kelly says on page 39, "I have emphasized the words of Dr. Fenwick because they represent the conclusion of the preceliotomy period in the history of the appendix when small incisions for the evacuation of pus were recognized as the proper surgical treatment."

While Dr. Fenwick's words conclude the "preceliotomy period" my notes, which you may see in the original, may claim to open "the surgical period," for *I acted* upon the conclusion recorded on March 30, 1884, on the first opportunity,* as follows:

*Discussion, by invitation, of a paper by Dr. Cruikshank, read at a meeting of the Medical Society of the County of Kings.

*See Wyeth Transact., N. Y. Acad. Med., 1884, and *Journal of American Medical Association*, June 13, 1907, p. 121.

On December 29, 1887, I was called to a boy of eight living in a fashionable boarding house on East Forty-second street. G. W. presented pain in the right iliac region, exquisite tenderness distinctly localized at the point now known as McBurney's; he lay with his legs elevated to relieve pain. Pulse 120, temperature 102.4°, respiration 36. I gave an unfavorable prognosis and informed the mother that if no improvement occurred in twenty-four hours I should call a surgeon to operate. The mother did not share my alarm, since she had seen him in similar attacks of "stomachache." His condition did not materially change during the day. Quoting from the notes I gave to Dr. Sands on the following morning) "his pulse was 130 and respiration 36" (*New York Medical Journal*, February 25, 1888). Although there had been no pain, no vomiting, and the patient was decidedly more comfortable, the continuance of exquisite tenderness together with dullness over the right iliac region, and the example of three fatal cases induced me to believe that the time for action had arrived. I requested to have Dr. Sands in consultation, deeming an operation necessary. The doctor saw the patient at noon and gave a very unfavorable prognosis of septic peritonitis with "belly full of pus." Having my three fatal cases in mind I insisted on surgical interference, whereupon Dr. Sands said that the only procedure he could adopt was a long vertical incision for the purpose of cleansing the peritoneal cavity. I objected to so heroic a treatment because it seemed impossible for the boy to have his "belly full of pus" when he had been in perfect health thirty-six hours previously. With consent of Dr. Sands I went for Dr. W. T. Bull and brought him to the patient. Dr. Bull agreed with me as to the pus. After some discussion a compromise was reached. Only a small quantity of pus, about half an ounce, was found, also a small concretion in the abdominal cavity, another in the slit of a perforation, and another escaped from the appendix. Dr. Sands cleansed the parts thoroughly, pared the margins of the aperture with scissors, and brought them together with interrupted sutures. These facts are corroborated in a letter from the late Dr. William T. Bull which I have here. I also have a photograph of the cicatrix which you may examine. You note that in this case the appendix was not removed and that, therefore, the history given in Dr. Howard Kelly's monumental work is correct in that Dr. Morton's case was the first in which the appendix was successfully removed for perityphlitis.

In the history of the case as given by Dr. Woodbury in the transactions of the Philadelphia County Society for 1887, it is designated as "Specimens removed by laparotomy in a case of the perityphlitis abscess in which the tumor was decidedly large, of potato shape, and suggesting intussusception." And in the *Journal of the American Medical Association*, June 16, 1888, Dr. Morton mentions this case among others as "pericecal abscess." There *is no mention made in either of these histories that a diagnosis of "perforative appendicitis" was made before operation.* On the contrary the whole history of the case shows that Dr. Woodbury had adopted for three days the same practice I had followed in three fatal cases—leeches and morphine. Intussusception is the only "probable diagnosis" mentioned. When Dr. Morton saw the case "the patient appeared to be dying." There was no alternative but to cut down upon the tumors.

Contrasting this case with my own operated upon by Sands, as reported at that time, it is clear that *mine was the first case of perityphlitis in which the family physician called a surgeon for the purpose of operating despite the fact that there was no swelling or other surgical indication.* I declined the heroic procedure proposed and accentuated this view by calling another surgeon and insisting upon an operation at a point over the appendix. There was no general peritonitis, only an ounce of pus, no abscess cavity. In fact, "my conclusion in 1884 demanded that an operation must be done to prevent patients dying from perforation" or lingering until an abscess has been formed by efforts of nature, and *this was the consummation achieved in the case operated upon by Sands.* I am sure that when Dr. Kelly reviews the data here briefly furnished by following them up to their source he will do historic justice to both Dr. Sands and myself by stating that this was the first case successfully operated on before an abscess formed or fatal peritonitis ensued. That is the chief point at issue.

So firmly impressed did I become by the result of insistence on operative procedure in this case that I took occasion to promulgate the surgical view of every case of appendicitis in our societies. To-day this is an accepted view, but it was not so twenty-five years ago. Brief outlines of some cases in my private practice demonstrate this fact. I should not occupy your time to mention them did they not also illustrate the fact that insistence on the surgical aspect and necessity for operative procedure probably saved the lives of patients when eminent surgeons who had been called into consultation deemed operation premature or avoidable. The general practitioner bears the brunt of responsibility in these cases. It is he who must make the first diagnosis at a stage of the malady when diagnosis is difficult and when he would lay himself open to the charge of being an alarmist, which is regarded a crime by many families. Doubtless many of you have passed through experiences similar to those I shall relate. It would serve a useful purpose if you would relate them to-night as a lesson to the rising generation and as an encouragement to be cautious but bold who always give the benefit of the doubt to the surgical aspect of the case.

Case I.—Mr. D., a strong young man of thirty-five, presented positive evidence of appendicitis. I applied ice as an anesthetic. This has become my practice because thereby morphine is avoided, the effect of which handicaps the surgeon in his diagnosis when called in later. Dr. W. T. Bull was called in at my request. I favored an operation but he twitted me with a penchant for seeing appendices removed. Yielding to his advice the treatment was expectant and the patient recovered.

Case II.—R., a boy of thirteen, fat and unwieldy, was attacked by general abdominal pains, which could be, on careful test, traced to the left hypogastric region as a radiating center. His temperature was 101° F. He had vomited and bowels had not moved in thirty-six hours. The case presented the aspect of an intestinal obstruction. I ordered calomel, which failed to act, then called in the late Dr. W. T. Bull. In the meantime a large turpentine enema was administered. This had just operated when Dr. Bull arrived. I greeted him with the jest that the trouble was over but asked him to examine the patient. After going over the case with his customary care, he surprised me by the statement that we had a case of acute appen-

dicitis, with the tenderness unusually in the left side. I could not agree and said that if he was correct I would not let him leave the house without a promise to return at once prepared to operate. Dr. Bull said there was no hurry and that we might treat the case expectantly for several days; that he had no doubt I would agree to the diagnosis in the morning. On the next day I saw the patient early and found Dr. Bull's view justified. There was decided tenderness on pressure in the right iliac region but very little pain without pressure. Dr. Bull was called immediately and I urged an operation, to which he assented if the consent of the family could be obtained. I decided to withdraw from the case if the family objected. The case was stated to the guardian of the boy and we suggested that anyone she desired might be called. There was no doubt that our view would be sustained. In the meantime Dr. Bull promised to do the operation at 2 P. M. A large hall-room was cleaned and thoroughly prepared, and when I returned at 1 P.M. an eminent physician had been called and had opposed the operation, saying that he might be called over at 2 o'clock from the Presbyterian Hospital where he would be lecturing at that time. The decision now being left with the aunt of the boy she reluctantly consented by reason of "two to one." The patient was on the table when our colleague arrived. He gave as his reason for objecting to the operation the recent case of his sister who had presented a similar condition and in whose case he had persuaded the surgeons who had prepared for operation to desist with the result that she recovered. Convinced that operative procedure was imperative I suggested to Dr. Bull to begin, the patient being already anesthetized, and I invited the colleague to see the result, which he declined because of his lecture, though positive of the necessity of immediate operation. I had no suspicion of the condition of the appendix until it was reached; certainly Dr. Bull had no idea that the appendix would be found gangrenous, barely allowing a ligature at its infiltrated base. Patient made a good recovery. What would have been the result if even a single day had been wasted on expectant treatment is obvious. What is the lesson? Here were besides myself one of the most skillful surgeons and one of the best physicians entirely oblivious of the fact that the patient's life hung by a thread by reason of gangrene and that the delay would have caused his life.

Case III.—Mrs. D., about fifty years of age, was seen in a second attack, the first having occurred at Bay Shore four months previously. I called Dr. McBurney who declined to operate until after the acute attack had subsided. I agreed to wait if he would guarantee recovery from the present attack. Naturally declining this responsibility, he agreed to return after dinner prepared to operate if there were no change for the better. Insisting on the operation, in the evening the appendix was laid bare, and we were both surprised to find perforation imminent. The patient recovered.

Case IV.—Mrs. H., at the Juvenile Asylum, West 176th street, presented all symptoms of acute appendicitis. I telephoned Dr. Lucius Hotchkiss to come immediately prepared to operate. He replied that he could not do so, but when informed that the case was urgent he arrived two hours later. This was long before the day of subways. He proposed temporizing, but when I transferred the responsibility to him he operated and congratulated me and himself on just preventing a perforation. Recovered.

Case V.—Mr. L. was seen also by Dr. Hotchkiss, who proposed to await developments. Not being able to attend the second consultation I sent him a message to operate. He preferred waiting until morning, when he and I were astonished to find three large concretions which were covered by appendical tissue of extreme tenuity. Recovered.

Case VI.—Mrs. B., married, two children, was attacked during the night by violent pain in the right iliac region which did not yield to morphine and demanded chloroform for several hours. The severity of the pain and absence of tenderness caused me to examine *per vaginam* and a small fluctuating round mass was discovered. Her gynecologist called at my suggestion and pronounced the case appendicitis, stating that he did not feel the tumor. I then sent for Dr. McBurney who, depending on the history of the case, pain having ceased, advised waiting. Three months later, at Long Branch, N. J., I was again called during the night and found her with agonizing pains demanding chloroform. Having dismissed the suspicion of ovarian trouble by reason of its non-acceptance of two specialists, I telephoned for an eminent surgeon who brought his assistants out on a special train at 3 A.M. He made a diagnosis of appendicitis. While cutting cautiously towards the peritoneum a sudden gush of yellow limpid fluid caused him to utter an emphatic note of surprise. This flow issued from a cyst of the broad ligament; the appendix was elongated and slightly red at its tip; it was removed; the surgeon who left for Europe saw her only once more, as she recovered in ten days.

Case VII.—Mrs. R., married, the mother of two children, was attacked with severe pains in the right iliac region for which she was seen by an eminent New York physician who resided in Long Branch. The diagnosis he made was ovarian trouble supplementing it with the statement that such symptoms in a man might arouse suspicion of appendicitis. This physician being compelled to leave, the mother of the patient telephoned me the above facts, urging me to come down. A diagnosis of acute appendicitis, probably perforative, was clear and a surgeon was asked for. The trains having stopped for the night, Dr. John A. Wyeth came on a special. The patient having suffered greatly she was under mild chloroform anesthetic when Dr. Wyeth arrived. The doctor was willing to accept my diagnosis and the patient was placed on the table; a perforated appendix and localized peritonitis were found. The patient was not aware of having been operated on until she discovered the bandages after recovery from the anesthetic. She made a good recovery.

Case VIII.—A boy of seven was ill for three days at the Scarboro Hotel in Long Branch with "inflammation of the bowels." He suddenly grew worse while his physician was absent in the city. I was sent for but also was absent in the city. My son, Dr. H. B. Baruch, elicited from the intelligent aunt of the child a clear history of acute appendicitis and offered to telephone for me, knowing that I would at once bring a surgeon down. They preferred to wait. When I arrived the case was hopeless, the abdominal cavity filled with pus. Reports of a few operations in such cases having at that time been favorable, I suggested a surgeon. This was refused until the attending physician's arrival. On my urgent suggestion a surgeon

was engaged tentatively. When the young doctor met me he could not agree to my prognosis, but "in deference to my age and experience," as he expressed it, he consented to a surgical consultant. An eminent surgeon came down on a special engine; he thought that if he had such a case under observation in his hospital he would wait, because there was evidence of the formation of a limiting exudation. This latter having escaped my tactus eruditus, I put the responsibility of leaving the patient upon him. The little fellow was taken to the Long Branch Hospital, where Drs. Woolley and Slocum assisted. The abdomen was found filled with pus —patient was in collapse, and died in twenty hours. Fifteen hours had been lost in delaying operation. This is the only death I have to record from appendicitis since I adopted the plan of advising operation in most of my own acute cases.

These brief histories clearly demonstrate the difficulty if not the impossibility of forming an exact diagnosis of the condition of the appendix, for the most eminent men were deceived on this point. I am convinced that in only a few cases a normal appendix has ever been found. When there is distinct tenderness over the region of the appendix, similar tenderness not being complained of when the skin in the region is gently pinched, the patient not having taken morphine, and there is ever so small a rise of temperature in the rectum, the case does not brook delay.

My fellow general practitioners present here tonight may sympathize with the gratification I felt in getting even with the surgeons by being called as a medical consultant in the following cases:

Dr. Dawbarn had a case of acute appendicitis suddenly arising in which he urged immediate operation; the family wanted a medical consultant. When I saw the case an immediate operation was advised. I was present and astonished to find in this very recent case complete gangrene of the appendix so that Dr. Dawbarn had difficulty in applying the purse-string suture ligature which he has contributed to the technique of appendicitis.

In another case that came from Texas to Dr. Wyeth, the latter called Dr. Janeway and myself to assist in the obscure diagnosis. His judgment that surgical procedure was not necessary was verified by our examination. Several years later this gentleman was introduced to me in Houston, Texas, as the man "I had helped to save from being butchered by the surgeons."

In conclusion I would express the result of my observation to be that the number of cases that have been sacrificed by timid procrastination outweigh far the cases in which a fatal issue may result from premature or unnecessary operation. Personal knowledge I have of only one operation in which the appendix was found normal and from which the patient recovered without difficulty. When in doubt, "operate" is a safe decision in acute appendicitis.

51 West Seventieth Street.

Neurotomy for Obliterating Endarteritis.—Marquis describes the operation done in a case of obliterating endarteritis of the hand to relieve the intense pain of the gangrene. The resections necessary for the hand are of the cubital and median nerves in the upper third of the forearm; of the radial before it gives off the external cutaneous; of the musculospiral before it traverses the superficial aponeurosis; and of the cutaneous internal brachial before its bifurcation.—*Archives Générales de Chirurgie.*

NOTES UPON A SO-CALLED PARASITE OF YELLOW FEVER (SEIDELIN).

By ARISTIDES AGRAMONTE, A.B., M.D.,

HAVANA, CUBA.

PROFESSOR OF BACTERIOLOGY AND EXPERIMENTAL PATHOLOGY, UNIVERSITY OF HAVANA; PRESIDENT, BOARD OF INFECTIOUS DISEASES, SANITARY DEPARTMENT, CUBA, ETC.

My absence in Europe until a very recent date kept me from coming across an article published by Dr. Harald Seidelin in the Bulletin of the Yellow Fever Bureau, Liverpool School of Tropical Medicine, Vol. 1, No. 7, November, 1911, pp. 229-258. It becomes my duty to take exception to several statements made by Dr. Seidelin in this paper, entitled "The Etiology of Yellow Fever," since the notoriety which its writer has recently acquired through his claim of having discovered the causative agent of the disease may to a certain extent incline other investigators in this field to accord more credit than is actually due to his opinion.

In order to bring more clearly before the reader the salient defects of the structure built by Dr. Seidelin for the purpose of pushing his claims, it may be allowed me to refer to them seriatim, as they appear in the above mentioned paper. In attempting to trace for us the "lines upon which further researches ought to proceed," Dr. Seidelin launches himself upon a most surprising and unjustifiable criticism of the experiments as performed by the U. S. Army Board (1900-01), of which I had the honor to be a member and am to-day the sole survivor:[1] experiments regarding which Professor Welch has said that they will always remain as models in the annals of scientific research. This attitude on the part of Dr. Seidelin is most remarkable when the consensus of opinion, both at home and abroad, is unanimous in that the demonstration of Finlay's theory by the U. S. Army Board, by the manner of its accomplishment and the results of its application, has been the greatest medical achievement of the Twentieth Century, of the greatest importance to the countries interested, from a financial and political standpoint, and conducive to the greatest saving of human life since the introduction of anti-diphtheritic serum.

Dr. Seidelin goes to the extent of misquoting several authors; for instance, when he states, referring to a paper by my co-worker, Carroll, that "fourteen results were obtained out of a total of twenty-three inoculations which were believed to fulfill the conditions necessary for successful experiments." The fact is that Dr. Carroll, to make matters clear, in the article referred to,[2] introduces two tables, one in which twenty-two negative inoculations are shown, under conditions plainly adverse to infection, and another in which fourteen positive results are recorded, where conditions of mosquito maturity and personal receptivity on the part of the subjects were favorable.

In appearing to defend us from the objections which he claims have been made to our experiments in that, as he says, "symptoms produced in the individuals submitted to inoculation were not characteristic of yellow fever," he makes the remark that "at least some of the cases presented evidently quite typical symptoms." As we reported at that time, all the experiments were submitted for diagnosis to a board of experts (Drs. Finlay, Guiteras, Gorgas, Albertini) and not one of them caused the least discussion.

We had eight severe and moderate cases, with black vomit, icterus, albuminuria, etc., out of fourteen, and Guiteras had three *fatal* cases and three severe ones out of eight positive inoculations. This hardly supports Seidelin's statement that "all the cases were remarkably light."

But his simulated defence of the Army Board is most effective when he writes "Now, taking for granted that the ailment produced was really yellow fever, the whole value of the experiment depends on the question whether it can safely be asserted that the infection could have been contracted in no other way than through the experimental inoculations." . . . "Nor is the importance very great of the negative experiments made with fomites, bed clothes, etc., used by yellow fever patients and soiled with their blood and discharges. The real point at issue is whether there existed any possibility of infection through water or air, the two media which were at that particular time considered most likely to convey infection." A very cursory reading of our original papers, in which the experiments are carefully detailed, will reveal to the least fair minded the fallacy of these suppositions, the absolute lack of reason for such doubts. In the first place, the infection could have been contracted in no other way, as the men lived, ate, and slept in the company of other equally non-immunes for a period, in no case less than nine days before being experimented upon, their attack promptly following their inoculation.

The value of the negative experiments with fomites, on the other hand, is certainly enhanced when we consider that an average period of twenty-four days under such circumstances failed to infect men who were afterwards experimentally infected thus proving their evident susceptibility to the disease.

As to the possibility of air or water infection in yellow fever, I think everyone will agree with me that it is, too late now, after the prophylactic results which stare the least observing in the face, to go back half a century and begin the discussion of what we know to-day are perfect absurdities. More than fourteen hundred non-immune men drank the same water and breathed the same air as our experimental cases of yellow fever at Camps Lazear and Columbia, and no other but our own occurred in the vicinity.

Dr. Seidelin stands alone, so far as I know, in believing that our experiments "can never be considered absolutely conclusive" because they have not been repeated in a country free from yellow fever, as has been done with malaria and papataci fever, and because the development of the parasite during its life in mosquitos has not been followed. Here I would like to say that, as far as yellow fever is concerned, the difficulty of transporting infected mosquitos, but above all the evident danger to life which the infection carries, should be to a right-minded man reasons sufficient to restrain the experimentation within certain limits and never beyond the sphere of its real usefulness, and this has fortunately been obtained. As regards the parasite itself, not only with reference to the mosquito is it impossible to discuss it in yellow fever, but even in man, in spite of Dr. Seidelin's contention, the organism is as yet an unknown entity and as far as ever beyond the reach of man.

Although allowing that "the evidence brought forward is very strong," Seidelin further says that "no absolute proof exists of the mosquito transmission of yellow fever," and after acknowledging the undisputed evidence of the various campaigns against yellow fever, he repeats "we are compelled to conclude that the transmission of yellow fever by means of mosquitos has never been proved beyond discussion, but that there are exceedingly strong arguments in favor of the theory." Coming at a time when the recent International Sanitary Conference (November, 1911) at Paris has passed a resolution that yellow fever can be transmitted only by means of the *Stegomyia calopus*, Seidelin's remarks sound empty of sense and devoid of reason. In his apparent desire to stimulate research he goes so far as to cast serious doubts upon the exclusiveness of the species stegomyia as the yellow fever transmitter, and also upon what we might call the antevenomous period of the infected mosquito.

Of course, further investigation in these lines can be of comparative advantage only, since the fundamental facts have already been laid down in such a decided and clear manner, but it may be well to consider whether the results to be derived from such research would warrant the exposure of individuals to this end.

The next point in Seidelin's brief summary is one which deals so intimately with the subject nearest his heart that we are tempted almost to forgive him for the subtle and careful manner in which he pretends to overthrow the hypothesis that the yellow fever parasite does not exist in the blood after the third day of the disease, a hypothesis which rests principally upon the experimental fact that said blood is not infective either to the mosquito or when inoculated directly in man. The very necessity for the elimination of this proven fact lies in that the bodies which Dr. Seidelin claims are the parasites of yellow fever, have so far been found in peripheral blood when taken from the fourth to the eighth day of the disease.

The sources of error which he suggests as capable of having misled the various investigators are, as may be seen, essentially imaginary: First, he supposes that the parasite may have two stages, one in which it can pass through a porcelain filter and another in which this is not possible; second, that the amount of 0.5 c.c. was too small in the undiluted blood experiments; but this is not the case, inasmuch as we caused a severe case of yellow fever with this amount, taken before the third day; third, that injection of blood, instead of serum, was not made; this is true regarding the work of Marchoux and Salimbeni, but in our writings we have carefully detailed results of injection of blood, serum and filtered serum;[3] fourth, Seidelin discusses the question of antibodies brought forth by Marchoux; fifth, he objects to the fact that all the negative cases were not subjected to inoculation in order to test their immunity, as though one test were not sufficient for such dangerous a demonstration; sixth, he attributes little value to the direct blood inoculation experiments made by the French investigators as in his opinion "they prove nothing with regard to mosquito transmission," after the third day. Dr. Seidelin here forgets that we had previously demonstrated the same fact in so far as when mosquitos were applied to yellow fever cases, after the fourth day they did not become infected, and only one of the several treated failed to do so when allowed to take blood before that period.[4]

Hereditary transmission of the infection from the mosquito to its offspring Dr. Seidelin is ready

to accept, forgetting to mention the negative experiments of the Marine Hospital Service Working Party (1904), in which more than ten attempts were fruitless. He further doubts of the care with which Marchoux made his experiments with the triturated bodies of stegomyias, very unfairly suggesting the possibility that the result obtained was caused by a mosquito infected by heredity.

Dr. Seidelin summarises the discussion as follows: "The transmission of yellow fever by means of the *Stegomyia fasciata* has not been proved according to scientific principles, but has been made probable to such a degree that it can be taken for granted for all practical purposes." Once having in his own mind sufficiently demolished the experimental work which has made the transmission of yellow fever by means of *Stegomyia fasciata* so probable, Dr. Seidelin in the second part of his paper endeavors to clear the field for the presentation of his own parasite—I mean the one he claims as the real and only parasite of yellow fever. He follows the same methods of discrediting the work of his predecessors, from Sanarelli through Thayer, Stimson, Beyer, Pothier, *et al.*, and then starts upon the narration of his own story.

He says, "already, in the first few cases which I examined I had the good fortune to find a few elements which appeared to be of a protozoal nature, and which belonged, as it resulted afterwards, to the largest forms observed." It is remarkable, to say the least, that from the first few cases which he examined Seidelin could already find bodies which attracted his attention, but certainly unbelievable that they presented such characteristics as to lead him to think they were of a protozoal nature. His good fortune will be fully appreciated by those who after hours of tireless observation, through the best microscopes, of hundreds of specimens of blood, from hundreds of cases, at a time when the parasite was known to be in the blood, have failed to see any of the wonderful bodies which Seidelin so easily and so readily found and so willingly accused of being responsible for the infection.

In most cases in which he claims to have missed the parasite, six cases, he blames it to a defective technique. His statistics are very interesting, but beyond belief to any one conversant with laboratory methods and results. If his claims were true it would be easier to diagnose yellow fever from the blood examination than diphtheria from cultures made of the exudates in the throat. The author himself is struck by the results which he gives as facts. He reports as follows: Positive cases, "about" 50; later, 25 positive and 2 negative; 6 negative cases due to defective technique; then 12 positive results and one negative, which add 07 positive and 9 negative. Seidelin states, "We have about ninety cases with positive findings out of a total slightly above one hundred."

After presenting us with this astounding resumé of his "findings" he says, "The essential question is whether sufficient evidence exists to prove the parasitic nature of the bodies described," and again I must differ with Seidelin very materially, for I believe that the essential question is whether all the bodies which he claims to have seen were really there in as great a number of cases as he claims. For if they were and as he says he believes, they constitute the causative agent of yellow fever, how to explain that so many investigators failed to see them? The fact is that Seidelin has been in Havana; he has tried to show us the parasite of yellow fever without success, and hence this paper prepared in a spirit of honest criticism, first, of his unjustified onslaught upon the work that has been accomplished, and secondly, of his unsupported claims to having discovered an organism which is not beyond the speculative stage even in his own mind.

I do not care to go minutely into an analysis of Dr. Seidelin's article, as this would require the repeated quoting of paragraphs which would make this paper unnecessarily extensive, but will only refer to a few points which clearly indicate the weakness of his stand, and shall briefly describe the stained blood smears which he was good enough to show me.

In the endeavor to establish specificity for the bodies found in his stained preparations Dr. Seidelin has to attribute biological characters to his parasite different from those of all known protozoa. A very curious fact is that there are no two "parasites" alike in the same slide. These strange bodies (which may well be foreign bodies in the strictest sense) seem therefore to be in all stages of their evolution, if they are animal parasites, and in the same blood drop one may see a body about three microns in diameter with another which is like a small pin point of chromatin (?) on top of a red cell.

It is interesting to note what flights of fancy a cold, reasoning, scientific mind may be put to by the goading stimulus of a supposed discovery. The unwonted scarcity of the bodies fathered by Dr. Seidelin is explained by him by calling attention to "what little we know about the relationship between the number of microbes in a given infection and the intensity of the intoxication produced." The examples which he presents to illustrate his doubt are most unfortunately selected. Tetanus is a bacterial disease, a localized infection of a severely intoxicating type, because of the poisons which the bacilli produce, and are absorbed into the system, while yellow fever is certainly not a local bacterial disease, but a generalized blood infection, more allied to malarial or other protozoal infections; in malaria or trypanosomiasis we find few or no parasites only at stated periods, but in the acme of the fever or in prolonged cases the protozoa can always be demonstrated by a careful observer.

In the same manner Dr. Seidelin would have us believe that his bodies, the nature of which is as yet unknown even to himself, differ materially from other pathogenic protozoa in that they are not infective late in the disease, preferring to think that the third day limit established by the U. S. Army Board and corroborated by later investigators, is incorrect. Such a line of reasoning cannot but lead to failure in the end.

In the chart which accompanies the article under discussion the author, as he candidly confesses, has "endeavored to arrange the figures in such a way as to convey a general impression of what appears to be at least a part of its evolution, although all these stages have never been observed in one and the same case." I do not think it is very needful that I should add one word of comment on such an evident cause of error; such a misconception would be directly conducive to fatal misinterpretation. After this declaration several pages of the original paper are devoted to building up an identity for the supposed parasite, a new genus is created, Dr. Seidelin acknowedging that "it would not be justifiable to include it in any of the established genera."

Not wishing to make this paper extensive beyond the reader's endurance, I will bring the subject to a close by noting down my personal opinion, based upon the specimens shown me by Dr. Seidelin last Christmas Day.

As typical examples of his parasite, he showed me four preparations, three of them stained blood smears and one liver section. Two of the blood smears contained one parasite (?) each (Nos. 5 and 11 of the chart), another one had two Seidelin bodies (Nos. 16 and 18 of the chart), a large one and a small one, and in the liver section was to be found a group of four bodies within a liver cell (No. 39 of the chart), and another presumably free and isolated in the interstitial substance.

The slides containing bodies like Nos. 30 and 37, which really look like some form of blood parasite, Dr. Seidelin said had been left in Liverpool and thus could not be shown.

The reasons why these bodies were not at all convincing to me of their parasitic nature are, concisely stated, as follows:

(1) The preparations, stained by the Giemsa stain, had been very poorly treated. So much so, that the leucocytes had not taken their due coloring, many eosinophilic cells remaining unstained while others were intensely so, showing evidently a faulty technique and therefore unreliable results.

(2) Dr. Seidelin's supposed parasite is present in very limited numbers in each blood drop, not more than three or four, all unlike, in each preparation, and we know that infective blood, in yellow fever, must contain a great number of parasites if the amount necessary for infection is to be a criterion.

(3) Experiments have demonstrated that yellow fever blood is not infective after the third or fourth day, while Dr. Seidelin's bodies have not been observed by him except from the fourth to the eighth.

(4) There is no reason to believe that the parasite of any infectious disease may be demonstrated in the blood at any period when this blood is not infective.

(5) If the bodies shown by Dr. Seidelin were evolution forms of an animal parasite, as he claims, we would find several of them at least in the same period of their evolution in the same smear, and they would therefore present the same morphological characters; while as it is, it is not possible to find two bodies alike in the same preparation, except in the liver section, in which they are all four inside a cell.

(6) There is no analogy, as Dr. Seidelin admits, between the supposed parasites and other organisms found in the blood of man or animals.

(7) Finally, it is impossible to form an opinion that will carry weight founded upon smears stained in such imperfect manner and with such an unstable reagent as the Giemsa stain, and less so when the various characters of form and size presented by the Seidelin bodies are such that they ought to be readily observed in fresh preparations of blood in which it would be easier to differentiate them from platelets and protoplasmic and nuclear cell fragments.

K STREET, VEDADO.

THE "KARELL KUR."

By FREEMAN FORD WARD, M.D.,

NEW YORK

Of the great men that northern Germany has given to the world one of the most brilliant was Professor Lenhartz. The originality of his ideas and his skill as an internist attracted attention from many lands. The Hamburger-Eppendorfer Hospital, almost a village in itself, owed everything to his presiding genius. His special forte was the resection of diseased portions of tuberculous lungs, but although this part of his work was marked by great boldness, and issued in excellent results well worthy the study of any practitioner desiring to be abreast of the times, I was more particularly interested in his so-called "Karell Kur" for diseases of the heart and disturbances of the circulation.

It was my privilege to visit his hospital some two years ago. Seventy-five physicians were working under him, exploiting his various theories, particularly with reference to this plan of treatment. He does not claim to be the originator of this method, but he has been so identified with its advocacy and extensive practice that it might well bear his name.

What most impressed me was the simplicity and rationality of the cure. I was astonished that it had not been more universally adopted and practiced by the profession for, notwithstanding Professor Lenhartz's eminence, and his identification with the cure, one hears little or nothing of it, even in Germany. I can attribute this only to the fact of its extreme simplicity, for had I not seen the cases in all their stages, and had I not witnessed the wonderful results obtained, I could not have believed that so much could be accomplished with such simple means.

We have all realized our helplessness in dealing with severe disturbances of the circulation—disturbances which the usual remedies fail to affect. When nitroglycerine, strychnine, cactin, digitalis, and its derivatives fail, on account of edema, dyspnea, or faulty absorption and elimination, the physician must scan the lists for help. If the usual and unusual drugs fail, he must resort to narcotics, and the final result of that course we all know too well. It is in such extreme cases that the physician welcomes the new, effective, and powerful remedy. As far back as 1866 Karell had originated the system now under discussion, but Professor Lenhartz was the first to exploit it and the very first to use it as a treatment for obesity. (This is disputed by Hirschfield, but the point may be left to those who are interested in chronology.)

In my visit to the Hamburger-Eppendorfer Hospital I was permitted to see a large number of cases in all stages of the cure, from their entrance to the hospital to their leaving it, and the observation gave me such a strong impression of its value that I have not failed to use it in my own practice, in suitable cases, ever since; and not only in the two classes of cases mentioned, but also in certain cases of indigestion and disturbances of metabolism which had failed to respond to older methods. I will

describe briefly the exact method followed by Professor Lenhartz in the Hamburger-Eppendorfer Hospital, and also, by permission, cite two or three of his cases, adding some of the modifications and changes, seemingly necessary in this country, together with the reasons therefor, and two or three cases taken at random.

The patient admitted to the hospital, suffering from severe circulatory disturbance, characterized by a rapid and irregular heart, dyspnea, edema, caused by incompetent valves and thickened artery walls, with high blood pressure and irregular and interrupted pulse wave, is at once put to bed, and for one or more weeks everything in the way of diet or drink is excluded except milk, which is given in the following manner: For the first six or eight days, 200 c.c. of milk four times a day at four-hour intervals. Occasionally this is continued for fourteen days, and in rare cases, for three weeks. The first question which may be asked is: "Will the patient submit to so strict a cure"? As a matter of fact, many do object at first and many questions are raised, but the patient will soon become reconciled. After the third or fourth day of treatment the patient feels so much better, lighter, and more comfortable that he is even averse to going back to the old diet.

The reduction in body weight depends upon the degree of edema and the length of time that the treatment is continued. This is seldom more than six or eight days, at the end of which time certain foodstuffs are added, so that by the third or fourth week the normal diet, with certain restrictions, is again established, but the liquids are never increased above 800 c.c. in twenty-four hours. The requirement for normal metabolism, for an adult at rest, is about 2000 calories, while the 800 c.c. of milk, with which the strict cure is begun, represent only 560 calories; therefore, it is evident that the difference between the intake and the requirement of normal metabolism is compensated for by the burning up and absorption of the surplus fat and water. The loss of weight, especially in cases of severe edema, is often astounding, and for the first six or eight days will often amount to two pounds, and seldom is less than one pound daily. Of course, a large part of this is due to the loss of water in the tissues as the edema rapidly disappears, to the consequent greater comfort of the patient. It is not difficult to understand that the tired and overworked heart is essentially strengthened and given fresh powers of endurance by this loss of weight which, as a rule, occurs in all forms of hydrops. Patients to whom it was necessary to give morphine or other narcotics to induce sleep and quiet, were able, after three or four days of the treatment, to remain quietly in bed, with a great accession of sleep and restfulness. Soon all narcotics could be abandoned, and no other remedies were used, except a wineglass or two of bitter laxative water in the morning to promote the intestinal functions.

One point deserving of emphasis was observed; namely, that cases which had been most rationally treated with digitalis and its derivatives without appreciable results, and who suffered severely with shortness of breath, again responded well to digitalis preparations, after six to ten days of the Karell cure. Not only did the edema disappear, but the natural power of the heart muscle, itself, seemed to be restored. In certain cases, therefore, it is advisable to combine these heart tonics with the cure treatment, always postponing the time of beginning them until after the latter alone does not accomplish the desired effect. Just here I would like to call attention to the fact that the new preparations of digitalis are used almost exclusively in the German hospitals, seemingly with good results.

Another beneficial factor during the first days of the treatment is the very marked increase in the quantity of urine. This was particularly well illustrated in the case of a young woman with renal insufficiency who came into the hospital with the loss of compensation and general anasarca. She was put on the strict Karell cure, *i.e.* 200 c.c. of milk four times a day, all other food and drink being absolutely excluded. During the first twenty-four hours she voided 2 liters of urine, and on the third day 4 liters. On the fourth day she had lost 9 kilos, or about 18 pounds in weight. On the ninth day she was able to sit up and was discharged from the hospital on the thirty-third day with compensation practically restored. A still more marked case, illustrating the value of the treatment, was one of both aortic and mitral insufficiency, with very small and irregular pulse, and heart extremely dilated. In this case the quantity of urine was 5200 c.c., or over 5 liters on the fifth day of the cure. The edema rapidly disappeared, and at the same time the body weight was reduced 16 kilos, or about 32 pounds, in six days; there followed also a strong, regular pulse. After sitting up, the patient developed a swelling of the liver with ascites, which, responding to agurin, the patient left the hospital with good compensation. In the first case the quanitity of urine fell to 800 c.c. with a specific gravity of 1006 on the sixth day; and in the second case the quantity fell to 850 c.c. on the ninth day, and to 450 c.c. on the fourteenth day of treatment.

Another case of severe myocarditis, general hydrops with angina pectoris, arteriosclerosis, and hepatic cirrhosis, also improved while the effects of digitalis were markedly increased, while before the cure all the digitalis preparations had signally failed. There were two cases of an extreme grade of hydrops with fatty hearts, and with very weak pulse and heart action. One, after thirty-eight days lost 25.5 kilos, with heart improved in strength and pulse in volume. The other with only a moderate edema, but very irregular heart action and cramp-like pains in the cardiac region, simulating angina, was entirely relieved of these distressing symptoms. Another brilliant result was shown in the case of a man forty-two years old with very severe disturbance of heart action. He drank 8 liters of beer and smoked twelve to fifteen strong cigars daily. After a course of four weeks' treatment he left the hospital in almost perfect condition. On entrance to the hospital he weighed 91 kilos and voided 1700 c.c. urine in twenty-four hours; specific gravity 1015. On the second and third days he voided 2300 c.c. and 2500 c.c., respectively; specific gravity 1010, and lost 5 kilos in weight. On the tenth day he had lost 16.3 kilos, and then practically held this weight of 74.7 kilos. On the sixth day of the cure, in addition to his 200 c.c. of milk four times per day, 50 grams of meat and 30 grams of bread were added; and from the seventh to the tenth day these were given twice a day; after the tenth day a gradual increase to a normal diet. Another case in which a most happy result was seen was a man sixty-five years of

age, with myocarditis, extreme edema, arteriosclerosis and emphysema. He had received digitalis preparations to the physiological limit. He had also been to Nauheim, but returned much worse. Notwithstanding all this the edema gradually increased until he was so large that he had to lie immovable in bed, and was almost moribund. The edema had extended over the sternum and under the arms. Cyanosis was marked, and orthopnea accompanied the bronchitis. Under the treatment there was in this case a particular increase in the urine, the edema, and particularly the dyspnea rapidly disappeared, so that on the tenth day he had lost 18 kilos. After twenty-six days of treatment he had almost a normal flow of urine, with good pulse, and was in a very good and comfortable condition. The urine, which was 600 c.c. on the first day, rose to 1200 on the second day; fell to 400 on the fourth day; shot up to 3000 on the sixth day, and then gradually fell to from 800 to 1200 per day. The albumin, which was 1½ per cent. on entrance, held to about that amount to the seventh day of treatment, then gradually diminished to only a slight trace on the tenth day and thereafter.

Obesity: I now wish to show how this treatment has wrought equally effective results in the treatment of obesity. We all know that there are many who carry an overabundance of fat and yet are capable of a great amount of mental and physical work. There are many, however, who as early as thirty or forty years of age begin to show the effects of obesity of even moderate degree, who feel dull, have dyspnea, who perspire on the slightest exertion or without any apparent cause, and in whom a progressive weakening of mental and physical power and the desire for work can be observed; with the appearance of insufficiency of the heart, it is time to take matters in hand. For a long time both the laity and the profession have been busy seeking the best and least dangerous reduction cure, and this condition has furnished to the quack a rich field. That all of the quick cures are in bad repute is well recognized by the profession, and only too often have the fears of the unwary on this point been confirmed. All cures more or less aim to prevent the body taking on more fat by underfeeding (restricting the diet) through mechanical work, massage, exercise, etc., to unload the system of water and to increase the oxidation of its own fat; therefore, it is easy to understand that all such cures must be under the physician's directions. This is necessary so that he may guard against all unfavorable conditions, and especially for the observation of the action and condition of the heart. Coordinately with the reduction, the amount of physical exercise and work must be regulated to the patient's condition, and only very gradually increased. The ability to spare, guard, and exercise the patient, in conjunction with the reduction, will reveal the art of the physician, for a process to be productive of the best results must leave the patient not weakened, but with progressively increased ability for the performance of his duties, to say nothing of the cosmetic effect.

I believe, though, it is possible with this method to rapidly reduce the patient with perfect safety, more than with any other; this claim is best sustained by proofs, when case after case, without any true edema can be reduced in the first six to ten days, from 10 to 15 pounds, and that without any distress to the patient. If concurrent with the falling weight, the secretion of urine is increased, one can feel that the prognosis is particularly good, especially so with patients who can be trusted to carry out the details as prescribed. Following, however, a considerable reduction in weight, we have a lowering of diuresis which day after day scarcely equals the intake of liquid. But we must consider that we have to do with a melting down or destruction of proteids and fat, though in the experience of Professor Lenhartz, who had, perhaps, to deal with more extreme cases than myself, and likewise in no case of my own, has there been exhibited any unfavorable or alarming symptoms. As a general resultant, the patient feels stronger and lighter and has more endurance; he can walk and breathe better and the heart action is stronger. Of course, there are patients with whom this treatment does not agree; others who wish to compromise or have not the faith and will power to carry out the directions, and still others who improve at first, and then for some reason fail to progress further. However, these cases are a small percentage. On the whole, this treatment, modified to suit each particular case, when properly carried out by physician and patient, has been most satisfactory to both. Moreover, it has been unattended by danger, nor is there any disturbance or any disagreeable symptom not easily corrected.

Many patients will offer the objection that milk always constipates them. To overcome this objection, I advise an India biscuit with each glass of milk, and that the patient should masticate it thoroughly, sipping the milk at intervals. This biscuit furnishes no nourishment whatever, but it breaks up the milk into finer flakes in coagulating in the stomach, produces more saliva, causes the patient to take the milk more slowly, serves to promote peristalsis, and also prevents the empty feeling in the stomach which occurs in some cases before the expiration of the four hours' period. Seldom will one need to resort to any other aid to the bowels, and often patients who have been chronically constipated all their lives will begin to have regular daily movement of the bowels on this treatment. Occasionally, one will have to resort to a mild aperient in the morning. The first case that I will cite is illustrative of this point and of what nature will do for one if she is properly treated and not overloaded each day with more work than she is capable of doing. This patient's bowels, you will notice, became regular from the first day of treatment, whereas she had previously been accustomed to taking a stronger laxative every night. And when I increased her diet which, in this case, I did a little too soon, she became constipated, but regular when put back at her own request on the strict régime. It also frequently happens that a man cannot give up business or a woman her social engagements without great inconvenience. In such cases we can modify the cure in one way and another and get most satisfactory results, but the treatment naturally would extend over a longer period; also the patient must be honest and faithful to this regimen, changing nothing without consulting his or her physician. As an illustration of the importance of the patient's fidelity to details, one patient started out nobly with a strict regimen and by the second day had lost 2 pounds, the urine had increased 50 per cent. in quantity, with a sediment of urates and uric acid. On the third day she was invited to luncheon and thought it would make no difference in the cure. She returned to

me on the fourth day and confessed, but with this little break in the cure the urine went down to 755 c.c., and she gained back the 2 pounds that she had lost.

Now the question that naturally arises is: Do not the patients immediately put on weight when they return to their regular diet? If the patients returned to their former diet, no doubt they would, but at the end of their cure, as a rule, it has been so thoroughly demonstrated to them just how much and what kind of food they need, and how much better they feel, that they almost invariably hold their weight and often go on gradually decreasing if they are still above the normal weight.

To sum up, as I stated in the treatment of the disturbances of the circulation, so I here repeat as applying this treatment to adiposity, that there will be cases of the latter which do not respond, or for some reason cannot or will not carry out this regimen, which cases might be put down as failures, but taken on the whole, it is a most satisfactory treatment and attended with the least or, in fact, no dangers. Before closing, I will give a few cases which will serve as an illustration of the treatment for adipositas without any special heart trouble, and of the modifications which sometimes aid in the cure and prove more satisfactory to the patient.

A lady, thirty-eight years of age, came to me, whose only complaint was that of overweight. Her weight was 222½ pounds, and as she was only 5 feet 6 inches in height, one could easily believe that she was very uncomfortable. She had taken several so-called cures, including a restricted diet, but very soon she regained what little weight she had lost, when she returned to her normal diet. I put her on a regimen of 200 c.c. of milk to be taken at 8, 12, 4 and 8 o'clock, with one India biscuit with each glass of milk. She was to take no other food or drink, and as it was impossible for her to keep perfectly quiet, and her heart action being rather weak, I gave, in this case, a mild heart tonic of digitalis, strychnine, and nitroglycerine in extremely small doses. On the third day she reported to me, when she weighed 217¼ pounds, a reduction of 5¼ pounds. She felt very much better, her breathing was easier, and her heart action was stronger. On the fifth day she weighed 214¾ pounds, a loss of nearly 8 pounds in less than five days. I increased her milk to 1200 c.c. per diem, and as she had to return to her home in Buffalo, I advised a gradual return to a modified general diet. After one week I received a letter from her, saying that she had increased her diet but did not feel as well as when she was taking only 200 c.c. of milk four times a day, and asked permission to return to that regimen until she could see me again. Another point in her case well worth noting is that when she resumed her regular diet she again became constipated, and that as soon as she returned to the restricted milk diet her bowels became quite regular. Ten days later she reported at my office, prepared to sail for Europe, weighing 208 pounds, and feeling better than she had felt for years. I advised her not to continue this diet longer than her trip on the steamer, and to return gradually to a restricted diet, which she did, and sent me a fine report of herself on her arrival.

Another case was that of a lady of forty-two, who notwithstanding exceptionally good habits as to eating and drinking and exercise, had gradually gained in weight until she reached 180 pounds. Her flesh was solid and firm and she had no organic disease nor any other trouble but that of adipositas. I put her on the strict regime of the Karell cure, and saw her about twice a week, and at the end of two months she left town in perfect health, weighing 164½ pounds.

I can mention many other cases, but these serve to show the process and the efficiency with very few exceptions of this method of treatment.

616 Madison Ave.

GONORRHEA: ITS PREVENTION AND CURE BY AUTOTHERAPY.*

By CHARLES H. DUNCAN, M.D.,

New York,

Attending Surgeon to the Volunteer Hospital.

In former papers the writer cited many diseases cured and prevented by placing the natural vaccines together with a portion of all the toxic products of tissue changes in healthy tissues. It was recommended in these papers for the first time the advantage of sucking all fresh wounds where possible when there was even a remote probability of the wounds being septic, or placing the discharge from all accidental wounds on the tongue (a lesson we learn from the dog that licks and cures his wounds) as the safest and best means of preventing sepsis. It was pointed out that when the crude pus from a septic wound is placed on the patient's tongue it would tend to cure the infection in the quickest and best manner possible (*Lancet-Clinic*, November 4, 1911). The writer has cured many of the most pronounced cases of sepsis by this method (Medical Record, September 16, 1911), by giving the crude autogenous pus by the mouth. He has cured puerperal sepsis, septic abortions, septic endometritis, furuncles, abscesses, postular acne, some forms of eczema, etc., and sees no reason why a skilled autotherapeutist may not cure very many extraalimentary and extrapulmonary diseases in a similar manner. It was also pointed out that many diseases may be cured by filtering the pathological excretion or discharge of the disease with a Berkfeld filter and injecting the filtrate hypodermically. In the present paper the writer will discuss a new method of preventing and curing gonorrhea.

In every scientific discussion we should be guided by facts and not by sentiment. There is no room in medicine for the physician who would refrain from giving his patient curative medicine on account of its not being pretty, or of associations in his own mind that make it abhorrent. A physician is justified in giving his patient anything that will cure him. But we do not have to search for a remedy that will cure and prevent gonorrhea. Provident nature places the prevention and cure within easy reach of the physician in the very form adapted by nature to be taken, and the only wonder is that this simple treatment was not discovered long ago. Every patient suffering with

*The writer is well aware that this paper contradicts much that is held to be true by those best qualified to judge in such matters. It is based on clinical experience, the court of last resort in determining questions relative to the therapeutic value of any medical preparation. It is not within the powers of any physician to investigate thoroughly all the avenues of thought opened up in enumerating the principles of autotherapy. The best the writer can do is to point out the way that others who have more opportunity may take up the work along their various specialties and work out each disease by itself along the lines suggested.

gonorrheal urethritis carries the cure for it with him in the discharge. The writer is well aware that exceptions may be taken to the method of treating gonorrhea he suggests, but let us stop right here and have a mutual understanding lest anyone should utterly forget the scientific nature of the principle involved in this discussion and thereby suffer his sensibilities to be shocked. If men and women will expose themselves to gonorrhea they are not in a position to object to a cure that may be suggested. This treatment is no worse than the disease itself. The writer is seeking the truth (as abhorrent as it may appear at times) in whatever highway and byway it may be. Any scientific investigation or deduction not founded on truth fails utterly in its purpose.

This method of treating gonorrhea is being developed by following the principles of autotherapy. This consists in placing the natural vaccines together with a portion of all the toxic products of tissue changes contained in the pathological excretions or discharge of the disease (or in other words toxic tissue poisons) in healthy tissues. Briefly stated, autotherapy cures many localized, loosely localized and possibly nonlocalized diseases with their own poisons. When a patient suffering from one of this class of diseases recovers without any external medication we believe he is cured by autoinoculation, that is the power of the serum is raised, the activity of the leucocytes is increased, the invaders are overcome, and the patient recovers. Autotherapy cures disease with the same weapons nature uses. It is the method the physician employs in assisting in arousing the natural forces within the body; they alone can bring about a perfect cure. The new method of preventing and curing gonorrheal urethritis is similar in its application to the method of preventing and curing sepsis previously reported. It consists in placing the crude autogenous discharge of the disease on the patient's tongue. This method of treating gonorrhea has a strong curative tendency in any stage of the disease. If given early enough it will abort gonorrhea.

Another method the writer suggests as possibly efficacious is filtering out the bacteria with a Berkefeld filter from the discharge or a solution of the discharge of the disease and injecting the filtrate hypodermically. This method of curing disease has a wide applicability. The writer has proved that many diseases that are now cured by opsonotherapy may be cured more quickly and often prevented by either one or the other of the two principles enumerated above. The first question that would naturally arise in considering the first method of treating gonorrhea is: Is there not danger of autoinfection, by placing the crude gonorrheal pus on the tongue? The next question is: Will it cure? Till we can satisfactorily settle in our minds the question of danger, we are not in a position to discuss the therapeutic effect. The question of beauty or homeliness of a method of carrying out a treatment has nothing to do with the subject from a scientific point of view, so we will dismiss this phase of the discussion at once. Anyone who has practised medicine for even a few years has seen or heard personally of a number of cases of gonorrheal ophthalmia. The oculist has seen many cases. If gonorrhea is infectious through or by the mouth, we would have seen more infected mouth cases than eye cases, for the hands go to the mouth many times when they go to the eye but seldom. Especially is this true if the patient is warned to keep the hands away from the eyes. We never warn them to keep them away from the mouth, and we rarely see gonorrhea of the mouth. Gonorrhea of the urethra often causes frequent micturition, and in the various toilets visited during the day for that purpose there is often no means for washing or cleansing the hands after the cotton or bag has been removed and replaced. Truck drivers, laborers, and those of the lower classes are not overcautious in this particular. They do not know the meaning of asepsis, they more frequently take a chew, or light their pipe, or even eat their meals after perhaps merely wiping their hands on their overalls. Yet we rarely see gonorrhea of the mouth in these individuals. Gonorrhea is highly infectious to the eye, but the writer has yet to hear of a case of infection of the mouth and throat following an infection of the eye. The tear duct drains the infected eye into the nose. The gonococci hence must come in contact with the nose, posterior nares, pharynx, mouth, larynx, and stomach, and in some few cases these regions would have become infected if gonorrhea is infectious to these membranes. Now the fact that we rarely ever see or hear of infections by the latter leads one to believe that gonorrhea is not infectious to the unbroken mucous membrane of the mouth, throat, and alimentary canal. Whether the nasal secretions or the saliva or the inhibitory action of the mucosa of the nose and throat is the cause of the immunity from infection of these cavities is a subject that will bear investigation. It is the ratio of infections after exposure to the escape that is our best guide in determining the relative chances of an infection taking place. If this ratio is very small, or fractional, or scarcely heard of, it may be considered as negligible, and need not be taken into consideration. Gonorrhea appears to be no more infectious on the unbroken mucous membrane of the mouth than the staphylococcus and streptococcus.

In looking up the subject further to discover whether gonorrhea is infectious by the mouth or not, the writer was surprised upon reflection to find that he did not recall a single case of gonorrhea of the mouth in a hospital practice in a district where if it were prevalent he would see it. He then made it a point to go with a company of physicians into the darker section of New York for the purpose of obtaining knowledge of it first-hand from the very people who are exposed to gonorrhea of the mouth many times during a single night. The writer made as careful an examination of the mouth as was possible under the circumstances of the ones he interviewed and saw no evidence of it. However, he did observe that nearly all had a mouth full of bad teeth, or few teeth or no teeth. Whether this had any connection with the gonococcus or not he does not know; it is a subject that will bear investigation.

Abundant observations conclusively prove that about all prostitutes are gonorrheal carriers, but we rarely see this disease to recognize it in the mouth. It may be, and it appears reasonable to assume, in the light of these investigations, that having the gonococcus in the mouth renders them more or less immune to vaginal infections even with the multitudes of gonococci in the vagina. There is no doubt that many of these women have at times gonococci in the mouth as well as in the vagina. Men at times kiss these gonorrheal carriers, and if the disease were infectious by the mouth

our young men and boys would have become infected in the mouth at least occasionally, but here again we rarely see the disease. The only conclusions that can possibly be drawn from the above observations is that the possibility of gonorrheal infection of the mouth is so slight as to be practically disregarded.

The next question to be answered is: Will there be a curative reaction in the tissues if the autogenous gonorrheal pus is placed on the tongue? The microorganism of gonorrhea is of the coccus family. Now the writer has proved that two members of the coccus family, namely, the staphylococcus and streptococcus, are curative in extraalimentary and extrapulmonary diseases caused by the organisms if the live autogenous microorganism is taken by the mouth. That is, the healthy tissues with which the microorganisms come in contact by way of the mouth, being remote from the seat of the disease, develop specific antibodies to the disease.

If autogenous gonorrheal pus tends to be curative by way of the mouth, we would expect its action to be similar to that of other autogenous products, that is, it would tend to act in a preventive manner as well (see MEDICAL RECORD, September 16, 1911). We would expect that if the physician gave it early enough he would be able to abort gonorrhea. If the above observations are correct, the application of the specific could be employed in a slightly different manner, more to the advantage of the patient and success of the physician than the treatment of sepsis. For on rare occasions in the male we could obtain the causative microorganisms from the infecting female genitalia. If the physician could do this we should expect that he would be able to abort the disease in the male. The reverse would also appear to be true, that is, he would tend to abort it in the female by administering to her by the mouth the identical causative microorganism from the urethra of the infecting male. Granting the above observations are true, it is readily understood that this should be done as soon after coitus as possible, both from a prophylactic and curative point of view.

This is in strict accordance with the writer's experiment in the prevention of sepsis and other diseases, and with the experience of Lux in the treatment of anthrax (1822) and with the experience of Wright and Douglass with autogenous vaccines, that is, so far as giving the vaccines early is concerned. Practically all authorities agree that the vaccine to be most efficacious must be administered early; stress is always laid on this point. So then we would expect that the administration of the gonorrheal excretion would be no exception to the general rule that governs the administration of other autogenous products.

This method of preventing gonorrhea would at times be helpful in preventing those fearful family tragedies we all have seen in general and hospital practice where the husband or wife infects the consort. Believing in the light of the above observations that there was sufficient ground to cautiously experiment, and realizing at the same time the possibilities of doing good, the writer decided to try it on selected cases. About this time there came to him for treatment a semi-prostitute. She had marked evidence of clinical gonorrhea; both Bartholinian glands were swollen to the size of the thumb. There was an extensive excoriation of both thighs. The whole vulva was swollen and pouty. The labia majora and minora were inflamed and rigid. From the majora the inflammation had extended to the cuticle on the mons veneris and the crease of the groin. The discharge was thick, yellow, copious, and came from the urethra. About half a teaspoonful was collected from the cervex and vaginal walls. Upon being told she had gonorrhea, she said she had two male friends whom she had exposed to infection a few days before. One of these was her employer, a married man. Could the writer give him some medicine that would prevent his having it? I told her I could if she sent him to me immediately. The next day he made his appearance. He had noticed that morning an uneasiness or a tickling of the urethra, and having previously had gonorrhea several times he knew the symptoms, and was under the impression he had the disease this time. He said he noticed a small morning drop. I told him if he would follow my instructions I would do what I could to stop it, and that I believed I could. This was the fourth day after exposure. I mixed the discharge with about half an ounce of powdered sugar as a menstruum. It made a thick paste. Of this I gave about one cubic centimeter by the mouth and told him to hold it there for five minutes before swallowing it. In half an hour I gave him a second dose, and in half an hour I gave him the third and last dose. I cautioned him against getting it in the eye, but told him to place any and all discharge he was able to obtain from his urethra on his tongue, and to return the next day. He reported the next day the tickling in the urethra did not stop; there was just barely a morning drop; there was no staining of clothes or other evidence of discomfort. On the tenth day he told me there was no tickling or abnormal sensation or evidence of the disease in any way, in fact there was no evidence of gonorrhea that the writer could in any way discover except a few shreds in the urine. In other words, the disease appeared to have been aborted. The writer upon close questioning obtained the bit of interesting information that the patient had been drinking on an average of three glasses of whisky and beer daily. Eighteen days afterwards the patient was enthusiastic over the treatment; he did not mind the treatment. "Would it cure?" was all he wanted to know. Satisfied in this, he was anxious to go the limit. Four weeks afterwards, when there was no apparent evidence of the disease, when he said he had entirely recovered, I gave him three more pills in a manner similar to the first three. The next day he said the disease was coming back, the irritation and moisture had returned. He said he had gonorrhea again, but he did not; it was the aggravation or the negative phase resulting from the medication. It cleared up in a few days. The writer believes this is proof that this medication taken by the mouth has a direct action on the urethra. He bases his conclusion of cure of this patient on the lack of demonstrable lesions in this patient, the history of the case, and the pronounced characteristic and other toxic manifestations of the disease both in the female and in the other male consort. A second case was that of a man, L. T. R., who appeared for treatment February 15, 1912. Exposed nine days previous. The first indication of gonorrhea was on the sixth day. There was a free discharge, the meatus was pouty and red, tingling on urination. Gonorrhea pronounced positive by Dr. Harlow Brooks of New York City. The patient was instructed to place the discharge

on the tongue. February 10 no change. He took the discharge several times. February 17, very much less discharge, inflammation subsiding, patient better in every way. February 18, a clean bag was put in place at 9 o'clock in the morning, and there was but a small amount of staining at 6 o'clock at night. No tingling on urination or other discomfort. February 22, the bag was just barely stained after twenty-four hours. This is a typical case and illustrates what can be expected of this treatment. In two weeks the discharge had stopped altogether.

The third case was in a married man aged forty years, who appeared at the clinic December 5, 1911. He had practically all of the symptoms of acute gonorrhea, following an exposure ten days before. Microscopical examination was positive. He had exposed his wife and was anxious that the writer should treat her also. I told him to send her to me as soon as possible. She came the next day. I placed some of the discharge in an ounce of water and shook it up well. She was given this to drink. I saw her at the end of one, two, and three weeks, and could discover no lesion or evidence of the disease in any way that could lead to even a suspicion of gonorrhea. A number of experiments of similar nature were performed in which the gonococcus was identified by the microscope. The result of all my observations of these cases indicates that when the crude gonorrheal pus from an infected urethra is placed on the patient's tongue it will tend to act in a curative manner. If the identical microorganisms be given early enough it will abort gonorrhea. If it is given two days after the discharge first makes its appearance, the microorganisms will disappear from the discharge in from twenty-four to forty-eight hours, the discharge itself will lessen, and usually disappear in from seven to ten days. When acute gonorrhea is treated by this simple method there is less chance of sequelæ in the shape of strictures, buboes, etc., than by any other form of medication, for the inflammatory stage is aborted or stopped early. Experiments in treating gleet by this method have not been very successful, although there have been no bad results.

A treatment so contrary to established precedents and a treatment that is so new and radical is bound to create more or less adverse criticism, and yet as we consider it in its various aspects the rational basis of this method appeals to the medical mind as agreeing with practically all we know of biological therapeutics. The writer would suggest to those who are disposed to criticise this method adversely that they withhold giving expression to their opinion until after they have given this method of treating gonorrhea a fair trial. Surely its simplicity must appeal to every one and it is within the power of practically every physician to test it for himself. If there is danger in placing the crude gonorrheal pus on the patient's tongue the writer has never seen it. He courts investigation of this method of treatment by anyone who will give it a thorough trial. The clinical symptoms are a good guide in determining whether the medication should be pushed or withheld. During the middle stage the indications are very similar to the indications for administering the vaccines, although the promptness in which its curative action is manifested and the good results following indicate at least to the writer that here at last is a true specific for acute gonorrhea. The writer believes that when the remarkable curative effect of this exceedingly simple therapeutic measure becomes widely known gonorrhea will be in a fair way to become exterminated. In looking further into the subject, the question presents itself: Will gonorrhea of the eye be aborted if the identical microorganisms are placed in the mouth at or about the same time the eye infection takes places? The writer does not know. It is evident the antibodies of this and many other infections develop faster than the infection, and the question to be solved is whether they will be developed when given by the mouth fast enough to overcome the eye infection or before they are washed down the tear duct into the mouth, and *thus keep up the negative phase of the disease*. If gonorrhea of the eye may be aborted in the same way as gonorrhea of the urethra, we have clearly at our command a new and effective weapon of combating ophthalmia neonatorum. The writer would suggest that this be thoroughly tested in the laboratory on animals. Let the microorganisms be placed in the eye and mouth of the animal simultaneously and the results carefully watched. If it is proved that gonorrhea of the eye can be aborted in this way the application to the mouth of the newborn child of the discharge from the mother could be easily carried out. After an eye infection is once established the patient in all probability will not be benefited by placing the discharge from the eye in the mouth. In gonorrheal ophthalmia of the adult the writer would suggest that a solution of the discharge be filtered and injected hypodermically in the manner to be described later.

If anything can be done that will help to lessen or wipe out the "social scourge," even to taking gonorrheal pus by the mouth, it will be a blessing for which humanity has long waited. Now let us see what other deductions can be made, what inferences can be drawn, what refinement of technique and administration may be introduced, and what grounds there are for these procedures. The first deduction is based on the prevailing opinion that the cocci are solely endotoxic in character. I wish to make a protest against this misleading textbook teaching. The dead bodies of the cocci are undoubtedly toxic, in fact there is more endocellular toxin than extracellular toxin in the staphylococcus and streptococcus, yet the writer has proved that sufficient extracellular toxins may be washed out of them with a small quantity of distilled water or when they are passed through a Berkfeld filter. These toxins may be injected hypodermically and will manifest a curative and abortive tendency. The writer has cured severe cases of sepsis in this manner, and sees no reason why all other diseases of the so-called furuncle group, that is, the large number of diseases caused by these microorganisms, may not be cured in the same way.

The following technique in treating sepsis was employed. From five to ten drops of the patient's own pus was placed in half an ounce of distilled water. This was shaken up well and allowed to stand at the temperature of the room for about six hours, when it was again well shaken up and filtered with a Berkefeld filter, and a few drops were injected hypodermically. The results proved that there is sufficient extracellular toxins or toxins developed by autolysis to act in a curative manner.

The writer was the first to filter out the bacteria from the pathological discharge of a disease and to employ the autogenous filtrate for therapeutic purposes. I would recommend that tests be performed in treating gonorrhea by employing this filter in a

similar manner. There is no danger of gonorrhea from an infective point of view if proper care be exercised during the filtration. No physician should hesitate in using this filter, for the act of filtering is simplicity itself. The filter used may be practically of any size. The one with which the writer has performed all his experiments is about the size of the thumb. It is possible that some bacteria may be strictly endotoxic in character. If this be so, we would not expect the filter to be curative in diseases caused by them. However, the writer does not know of any microorganisms that are strictly endotoxic or that will not develop toxins by autolysis. On the other hand, there are good reasons to believe that there are few if any bacteria that have not enough extracellular toxic substance to act in a curative manner. If this be so, the use of this filter in infectious diseases appears to be almost limitless. This filter appears to be applicable to practically all localized, loosely localized, and possibly nonlocalized infectious diseases. The use of the filter is limited to diseases whose causative bacteria do not go through the filter. Here the limitations are very few, for we know of no diseases of the group above mentioned whose causative bacteria would not be filtered out of the discharge of the disease and there are but comparatively few pathological microorganisms of other infectious diseases that will not be caught in the filter. A filter of this kind will last for years if it is properly taken care of, although it should be tested from time to time by making a culture from the filtrate. The porcelain is practically the only part that needs attention, and if it is thought necessary a new one may be purchased for every patient, as the cost of this part is only $1.25. The filters are all tested and guaranteed before they are sent out. In using this filter almost the very last drop may be utilized. The pores are cleansed by reversing the filter and running distilled water through it. It should be properly boiled before and after using. The writer uses a small electric burner for this purpose. The range of application of this filter appears to be very great; to just how many diseases it will eventually be proved to be applicable, clinical experience and laboratory experiments alone will tell. Autotherapy is not a cureall. The natural defenses of the human body include an attempt to throw off the toxic substances developed during the course of the disease. It is for this reason that the poisons of the disease are found in the discharges. When they escape into healthy tissues the power of the serum is raised, the activity of the leucocytes is increased, and the patient tends to recover. This is called autoinoculation and is nature's method of curing the disease. Riviere (*Proceedings of the Royal Society of Medicine*, February, 1911) states that when nature cures a severe infection it is on account of the toxic substances radiating or escaping from the inflamed area into healthy tissues. When the toxic substances are placed in healthy tissues by the physician the development of the same antibodies takes place as when they escape in healthy tissues by autoinoculation, the toxic substances in each instance tending to bring about a natural cure. For this reason this writer calls this treatment autotherapy. The healthy tissues resist or build up antibodies to these toxic substances, which antibodies are specific to the disease. Both autoinoculation (nature's method of curing disease) and autotherapy (the physician's method of assisting nature in curing disease) tend to bring about a natural cure, with the difference that the advantage is in favor of autotherapy, for it develops resistance to the disease earlier than the slower natural method. Autotherapy tends to shorten the course of or aborts the disease. The system is not then so charged or taxed with toxic substances. It is not reduced by prolonged fever. In other words, the powerful secondary defenses, the antibodies, developed by the healthy tissues, are brought into action early, and the time of the sickness is shortened. The question may be asked: "What are the toxic substances in the focus of infectious against which the healthy tissues react in a curative manner? Bail developed the doctrine of aggressins. He showed that the tissue toxins greatly intensified the pathogenic action of bacteria. He found in the focus of an infection (1) the toxic substance derived from the causative microorganisms, and (2) many enzymes, ferments, and toxic results of chemical changes in the protoplasmic molecule. The healthy tissues react against these tissue poisons, as well as against the toxic product of the bacteria. These are the substances the tissues use in bringing about a natural cure. These are the substances the tissues need in order that they may develop specific antibodies and abort or cure the disease. These observers claim that it is the latter toxins that cause wound fever in clean wounds. Their work was a scientific investigation and was not utilized (if I am correctly informed) from a therapeutic point of view until the writer began this work. The bacterial toxins or vaccines to be most efficacious must be used in conjunction with these tissue toxins. The writer was the first to place autotherapy on a firm and scientific basis.

Before closing we will take up some of the points of superiority which autotherapy offers over opsonotherapy.

The immortal work of Wright and Douglas in the treatment of infectious diseases has been welcomed by the medical profession as being one of the greatest therapeutic advances in the history of medicine. The writer believes the greatest thing they discovered is the fact that the vaccine to be most curative must be autogenous. The autotherapeutic method of curing disease is more curative, less dangerous, better, cheaper, and more convenient than opsonotherapy or the method of Wright and Douglas developed for the following ten reasons: (1) We are warned by many high authorities of the danger of anaphylaxis by giving repeated injections of the dead body of the bacteria hypodermically. Anaphylaxis enters into their hypodermic method of administration. The body of the dead bacteria are foreign proteid. Beef serum or whites of egg repeatedly injected at stated intervals will kill the patient by anaphylaxis. Yet these two are stable articles of food and there is no anaphylaxis when taken by the mouth. The dead bodies of the bacteria are not injected hypodermically by the writer's method. He utilizes the poisons of the bacteria injected hypodermically. Anaphylaxis does not occur in the autotherapeutic method of cure. If there were no other advantage of the direct, or the writer's method, over the indirect, or the Wright and Douglas method, eliminating the danger of anaphylaxis is sufficient to warrant its selection. (2) Vaccines lose in therapeutic value by heat. This does not hold true in giving the natural vaccines or the autotherapeutic toxins. (3) Vaccines lose in therapeutic value by being grown in foreign culture media and by being grown

outside of the body tissues. This does not hold true by giving the living virus by the mouth or by injecting the filtered toxins of the disease hypodermically. If a culture medium is necessary, one may use the patient's own blood, which is usually an ideal culture medium. The power of the serum is usually low, and the only wonder is that it has never been employed before for autogenous vaccination. Using the patient's own blood as a culture medium is distinctly an autotherapeutic procedure. (4) Vaccines lose in therapeutic value by time. By the direct method it is not necessary to wait from one to three days in sepsis, or five or six days in gonorrhea, until the pus has made its appearance, and then wait from one to three days while the vaccine is being prepared at the same time that the patient is growing worse. But the patient may be given the natural vaccine earlier than it can possibly be done by the autogenous method of vaccination now in vogue. By the direct method the different stages or phases of the disease may be met with the corresponding vaccine. This cannot be done so accurately by the indirect method or any other method of administering vaccines. (5) In the indirect method, or the Wright and Douglas method, the therapeutic value of the vaccine may be lessened by extraneous matter or foreign bacteria. This danger is a live one and great care must be exercised that it does not occur. Any one who has attempted to prepare a vaccine by the Wright and Douglas method knows this danger. Again in growing the single microorganisms in culture media we never know whether we have the one that is doing the most damage or not. There may be two or three at work at the same time. There is practically no danger from this error by my method. (6) The method of preparing and administering vaccines by the method now in vogue is not always within the power of the patient to purchase. This is especially true of poor people and people living outside of the cities. The cheapness of the writer's method places the already prepared natural vaccine in the hands of every one, however poor he may be; at most it takes but a few minutes to filter it. The merest waif of the city streets is as rich in curative medicine when he has a localized infectious disease as the most aristocratic millionaire or king. There is no money distinction here. (7) The method now in vogue of preparing vaccines is not always convenient. By the method the writer is developing we find that nature places the specific for the infection in the infected area in the very form nature intended it should be taken. Wherever there is an infection there in the infected area is the cure always at hand ready for use. This cannot be said of the Wright and Douglas method or any other method. (8) The Wright and Douglas method demands a skilled pathologist, one on whose report absolute dependence can be placed. He is not always easy to find. The direct method requires no pathologist. (9) The Wright and Douglas method requires a well-equipped laboratory. The direct or the autotherapeutic method requires nothing but our fingers or the simple Berkfeld filter. This is nature's method of curing infectious diseases to which the Wright and Douglas method is but an approximation. (10) But the greatest reason autotherapy is superior to opsonotherapy is that autotherapy employs the natural vaccines and a portion of all the toxic products of tissue changes against which the tissues react in a curative manner. Opsonotherapy does not do this. Autotherapy uses nature's weapons in fighting disease. By using nature's weapons we but assist in arousing the natural forces within the body. These forces alone can bring about a natural cure.

[The writer is indebted to a number of his confreres and co-workers for able and friendly criticism of this paper, for which he wishes here to express his thanks and appreciation for the time consumed and interest manifested in the work he is developing: Dr. Brooks, pathologist, New York Post-Graduate Medical College; Dr. James Ewing, pathologist of Cornell University Medical College; Dr. George Laidlaw, professor of diagnosis and internal medicine, and Dr. Wm. H. Freeman.]

233 Lexington Avenue.

SOME INDIVIDUALIZED ASPECTS OF PREVENTIVE MEDICINE.

By HAROLD W. WRIGHT, M. D.,

NEW YORK.

This being the age, pre-eminently, of the prevention of disease, physical, mental, moral, and sociological, we are all concerned in the campaign, whether we like it or no. In our zeal to do something great, to take part in some big movement, to prevent trouble wholesale, we are quite apt to overlook the little things that count for much, to forget the individual because of our concern for society as a whole. Even physicians are prone to this error.

But society is made up of individuals; society is, like the human body, an organism; if one member suffers, all, or at least some other members, suffer with it. What are the most important and most frequent individual problems confronting the general medical practitioner which have a direct bearing on the prevention of future disease and misery? Naturally, the answer is those which are seen in connection with infancy and childhood.

Who is confronted with them most often and in their incipiency? The obstetrician and the pediatrist, whose specialties are also the busiest fields in the work of the general practitioner, who alone has the best opportunity for prolonged observation and the drawing of conclusions from adequate experience. He it is who can follow a patient from the cradle to the grave, if given the chance.

In these days of specialties there is apt to be a great deal too much shifting of responsibility from one specialist to another and a disregard of anything outside one's particular field, and consequently an overlooking of many important conditions occurring in early life which have much to do with a child's future from every point of view.

To come down to specific matters, since the individual aspect of the subject is the one we are to consider, let us look at the period of earliest infancy.

1. How many congenital deformities are treated as soon as they can be and should be; and, if treatment is delayed, how much following up or supervision of them until treatment can be procured? How many are forgotten until irremediable or much more difficult to remedy? (Congenital clubfoot is an example.)

2. Are cases of congenital syphilis always recognized early, and if so, is treatment always persisted in until cure is certain? Think of the future consequences of neglect of this disease!

3. Nutrition of infants: What effort does the private physician make to secure breast feeding of every infant he sees? Or rather let the primary responsibility be put up to the obstetrician who delivers the mother, who may have seen her several weeks before labor, and almost always sees her for two weeks afterward. What effort does he make be-

fore the labor to have her in a condition to make nursing possible and how much supervision and encouragement does he give with this end in view for the few weeks after? When the woman leaves his care how often the problem of the child's nutrition is left to anyone who happens along, usually the neighbor who thinks all children are like her own or who feels quite competent to advise the young mother because she has "had twelve young ones and buried ten of them!"

Many children can be breast-fed who are not so blessed. Many bottle-fed babies get their feedings on a haphazard, guess-work, ill-advised plan and so never grow up vigorous, for it is in the period of infancy, when the growth of all the tissues and organs is most rapid, that the danger of improper food is the greatest. It is in this period of life that the foundation for chronic indigestion, a delicate stomach, and generally poor resistance to all the infectious diseases is laid, because nutrition is below par.

We can never hope, or at least not for many generations, to wipe out all the pathogenic bacteria in this world, but we can fortify people against them if we begin early enough. There is no greater or more interesting problem in preventive medicine than that of the nutrition of infants and young children. If their nutrition has been all that it should be during these periods little fear need arise for their physical welfare—gastric, pulmonary, or cerebral—in the years to follow; providing, of course, that they are free from inherited defects of structure, but many things called "hereditary" are really only things *very early acquired.*

Surely the subject is important enough to warrant the present status of infant feeding as a special study but not one to be neglected by the general practitioner because it requires some special study and attention to detail. It is not such a profound or intricate subject that only peculiar minds can grasp it. On the contrary, I venture to state that the subject could be so taught in our public schools to the young girl who will before long be deeply concerned about it that every high school girl graduate would be prepared to see her children safely through their early years of life when the food question is of so much importance, without the aid of a physician, nine times out of ten.

To leave the subject of nutrition of infants—we come to another condition often overlooked because so irregular in its manifestations—that protean disease, *rachitis.*

This disease is readily recognized after most of the damage has occurred, when several of its characteristic signs are present. But this disease has many latent symptoms in its earliest stages which can easily be overlooked. If the disease is recognized then, much future distress to the mother and many operative procedures or prolonged courses of orthopedic treatment upon the child may be avoided. To be recognized so early the disease must be borne in the physician's mind whenever he has the opportunity to visit any infant, for its frequency in all classes of society is much greater than is commonly supposed. One of its earliest symptoms is constipation, and many such cases are treated with cathartics or other local measures when a proper dietary would not only cure the constipation but prevent later manifestations of rickets of more pronounced degree. Indeed, may not much of the chronic constipation and generally feeble musculature of young adults, including those cases of myocardial insufficiency observed in children when they begin to attempt indulgence in school athletics, be due to this disease, present in a latent form in infancy? For rachitis is not, as so often incorrectly supposed, a disease of the bones only, but a disease of the entire connective tissue system, bones, muscles, blood vessels, lymph channels, and white matter of the central nervous system (hence convulsions and spasm of the glottis so often observed in rachitic infants). Small hearts and flabby hearts, small blood vessels and feeble circulation, and hence defective growth of the entire body, may be traced to this disease or an allied condition of defective nutrition and find frequent illustration in the numbers of under-sized, anemic, round-shouldered, and scoliotic children which one may see in every school room if he keeps his eyes open.

The remedy, or rather the preventive for such conditions, is a dietary suited to the individual child during its most rapid periods of growth, which shall contain all the protein and mineral matter necessary for that child. Such food constituents are not present in every mother's milk, after the sixth month in few, nor can they be utilized from average formulas of cow's milk by every infant. Each child must be studied individually and intensely if best results are to be obtained.

Some of the conditions enumerated above, such as the cardiovascular anomalies and the defects of stature, are often called "congenital." A more correct designation would often be "early acquired."

Another condition seen later on in childhood, but apt to be overlooked, is secondary anemia due to intestinal parasites or more often still to chronic intestinal indigestion. Such cases are observed soon after the age when the child's diet is considered no longer a specialty, and the age of 5 to 12 years is one in which the majority of parents let children eat what they want and whenever they want it. This is the age of appendicitis, acute and chronic, but pre-eminently the age of chronic indigestion of the intestinal type, victims of which are illustrated by the pale, sallow, peevish child with capricious appetite, constipated at times, at times having diarrhea, generally suffering from headache, lassitude, cold extremities, and disturbances of sleep (nightmare, grinding of teeth), even convulsions and incorrigible traits in behavior, facial tic, habit spasms, and general unhappiness.

It is from such children that, if the dietetic mismanagement is uncorrected, the neurasthenic, psychosthenic, querulous, and sexually abnormal young adult is produced.

What are we doing for such conditions? Mothers of all classes, but perhaps especially the busy mothers of the working class, need instruction in what foods should be given and how they should be prepared for children between the ages of 5 and 15 years. It is not always or usually a question of cost but a question of knowledge, for the faulty method is the more expensive. Dietetics has not yet invaded the school curriculum—it ought to. It has not yet become a popular subject for popular lectures, but why shouldn't it be?

We are teaching physical culture in the public school by practical methods, but of what use is physical training to those who have no foundational material for it because they are badly fed? I wonder how much of the mental retardation of school children could be traced to this cause. I do know that many a child comes to school on a breakfast of coffee and a bun and rushes home to partake hur-

riedly of a lunch of similar value, or else gets it at a bakery whose wares are produced on the "get-rich-quick" principle.

Children who are adequately fed as to time of meals and quantity and quality of food do not have capricious appetites, are not nervous or anemic, and the dietetic habits formed in childhood persist into adult life, so tending to prevent excesses and perversions in meat and drink later on. It is the badly fed person who has to resort to artificial and dangerous forms of stimulants in which he is necessarily prone to excess.

Our schools teach many things of more or less value. Is it more valuable to a child to know the apothecaries' table, the history of Rome, the number of our deceased Presidents, how to measure the wall paper of a room, and of less importance that he know the laws of health? Hygiene is taught in a measure, so is physiology, but I fear more emphasis is given to theoretical considerations of physiology and hygiene as related to disease than to practical instruction with actual demonstrations in the physiology of health, of which dietetics is the most important branch.

What are we as physicians doing to bring about a more efficient method of instruction in these matters? What are we doing with the children of our families in private practice?

Before closing let us consider briefly some conditions involving the central nervous system, and among those of chief importance are the deformities following meningoencephalitis and anterior poliomyelitis. These deformities are very frequently encountered. Let us hope that they will be less often seen in the near future not only because our laboratory workers will have found sera for inoculating children against these diseases, but also because the family doctor will have taken the trouble to learn how to prevent the deformities resulting from them, and will have sufficient interest and patience to see that such preventive measures are carried out.

In regard to poliomyelitis, deforming contractures are *always* preventable. There is no question about this. It is possible to prevent them if treated consistently from the outset of the disease. There should be no occasion for the operation of tenotomy following months or years after the outset of poliomyelitis. If the paralyzed and the opposing strong muscles are treated early and for a long enough time, deformity can be prevented. We may still have to resort to apparatus or tendon transplantations for the permanently paralyzed muscle groups, but we can prevent the deformities, and it is the deformity which causes most of the defect in function of the part concerned. Occasional massage or electrical treatment will not accomplish this, but persistent muscle training will, combined with the former measures, or even without any electrical treatment. The best authorities agree that concentration of the patient's attention upon attempts at voluntary muscular action and coordinate motions will accomplish far more than electricity. This should be combined with passive motion and massage and simple apparatus to prevent the pull of stronger muscles during sleep, and apparatus to enable the patient to get upon his feet and use what muscular power he has. But such treatment must be given daily and for months or even years, just as we must give thyroid constantly in cases of cretinism. Of course few patients' families will be able to afford such long treatment at the hand of trained attendants, but there is no reason why the parents of a child so afflicted cannot be instructed in the method.

In regard to the deformities resulting from meningoencephalitis, the results cannot be as good as in poliomyelitis because of the location of the lesions, but much can be done nevertheless to reduce deformity and incapacity by special training, in orthopedic schools preferably. The writer has seen in a young girl a spastic hand made capable of using needle and thread, and together with improvement in the use of the hand has come improvement in the mental condition, as could be expected because of the close relation between the use of the hand and the development of intelligence. Such patients are very often neglected and so become chronic invalids, defective in interests and capacity for enjoyment just because they are regarded as hopeless cases. We see the same results of neglect in the congenitally deaf or blind child, for whom a great deal can be done and has been done under specially skilled training. Visit some of our schools for the deaf-mute or the blind and you will be rewarded.

Organic lateral curvature of the spine is as distressing a condition in its last stages as could be imagined, but this, too, is preventable by early treatment.

We also want more information about and study of the abnormalities of the thyroid gland and the pituitary gland, and their relations to obscure metabolism and bodily structure, to defects of the brain and the vascular systems.

But before leaving the subject of neurological disease and its results it is in order to point out the need for more early and more accurate diagnosis by the general practitioner of diseases of the nervous system, and consequently earlier and more successful treatment of them. In this connection I would mention particularly the early diagnosis and early treatment of locomotor-ataxia, general paresis, and cerebral syphilis. Where seen in their advanced stages these diseases are not benefited by any treatment; but many cases ought not to reach the advanced stage. Some will reach it in spite of the most skilled attention. There are other cases, however, in which the most distressing and incapacitating effects of these diseases can be arrested.

It is surprising how few general practitioners think of making a systematic neurological examination as a routine procedure in every patient presenting obscure symptoms of pain, neurasthenia, vertigo, and general lowering of physical and mental efficiency. Many a case of incipient tabes or paresis has been treated for months as a case of "neurasthenia" or "neuritis" or "rheumatic neuralgia," or, if in the female sex, as a "disorder of the climacteric period." A careful examination of the pupils, tendon reflexes, and cerebrospinal fluid would have prevented such errors and also have allowed the patient the benefit of early treatment by medicine, hydrotherapy, and change of occupation. Vigorous mercurial and especially iodide medication, combined with general hygienic measures and a relief from the customary responsibilities of the patient's daily work, will avert indefinitely the dementia and physical disability seen in advanced and neglected cases of dementia paralytica and cerebral syphilis. The writer recalls a patient who when first seen was unable to do his day's work as a bricklayer because of the vertigo, irritability, and general nervous weakness accompanying diffuse cerebral syph-

lis. The man was given large doses of potassium iodide and moderate doses of mercury, both of which have been continued, the former gradually increased in amount, and today he is earning the usual wage of his trade without complaint although he is over 65 years of age. His mental condition has improved most noticeably and the physical signs are less pronounced.

While such results could not be hoped for in many cases of general paralysis or in all cases of cerebral syphilis, yet we can do much for the former class by early treatment, for this disease has a natural tendency toward remissions and the occurrence of unfavorable symptoms can be delayed by antisyphilitic and tonic treatment.

With regard to other forms of mental disease there opens a large field not only for the psychologist, especially the student of the psychology of childhood and adolescence, but also a field well worth the interest and study of the family physician. There are always causes for mental breakdown other than hereditary defect; this latter is undoubtedly present in almost every case, but only as a predisposing cause. The more we learn about the exciting causes the more we can do to prevent mental disease from progressing to the dangerous phase known as "legally insane." The problem is one involving child study and individualized education, vocational training, and an environment in which the individual is understood and has the benefit of intelligent sympathy and help which are as often lacking toward those who are at all peculiar in their mental makeup. "First aid" to the mentally unbalanced is of more importance than first aid to the physically injured. Too often the first treatment of these unfortunates is the worst possible, consisting in thoughtless cruelty and aggravation of symptoms by those whom they come in contact with in their daily life. Why is it that less sympathy is shown for and less shame felt in tormenting the mentally peculiar than would be given to some trivial physical complaint or injury? Such will nowhere be true when the facts about insanity, its causation, and treatment are as widely understood as the facts about tuberculosis have already been made known and appreciated.

The prevention of both the neuroses and the psychoses, the lighter and the more serious forms of mental disorder, is closely connected with the education of the child from the age when self-consciousness begins to the age of maturity, and the connection is especially related to the moral and religious education. It is well that theoretical instruction be delayed as long as possible, that the period of infancy and immaturity be prolonged as much as possible, for that is the natural order of development, as we can see in the evolution of our species. But there must be religious or ethical training of some sort from the age of self-consciousness onward through life if men are to be whole men and not merely higher animals. Such training for young children is better by example than by precept; later, when precept must also have a place, the emphasis should be much more upon righteousness than upon sin. It is always better to teach the love of what is good than to arouse curiosity and fear about the evil. Love will always conquer—it is constructive; but fear and hate are disintegrating and destructive of peace of mind. Many a case of adolescent insanity can be traced to morbid religious fears and doubts which the child has acquired from a distorted moral education; the very acts and utterances and delusions of the patient show this. To be sure, many children happily outgrow the fears inspired by morbid religious education, but alas! at the cost of cynicism for anything spiritual and the loss of faith in a higher power, of which they will surely stand in need in days of suffering and despair. But many more have a predisposition to mental unbalance inherited from ancestors, and this predisposition is increased by an early education which has laid the emphasis upon fear, punishment, and repression of activity instead of upon love and its expression in every healthful channel; such natures have become all too soon mentally and morally warped and denatured, so that only some physical illness such as influenza, typhoid, or in the case of young girls the disturbance of the menstrual function during its establishment, or even a normal childbirth is sufficient to suddenly bring about catatonia, acute melancholia, or mania. Sometimes there are other causes, such as sexual indiscretions, but it is the lack of trust, the fear of punishment, and the seclusive nature of the patients fostered by their early training which is really responsible for the mental symptoms.

To the question, "What is to be done about it?" the only answer is to say that the family physician, the clergyman, and the teacher must inform themselves adequately in the subject of psychology in order that each may in his place be competent advisors to parents and children at times of special stress and danger."

126 East Fifty-ninth Street.

WHEN CYSTITIS IS NOT CYSTITIS.*

By J. BAYARD CLARK, M.D.,

NEW YORK,

ASSISTANT GENITOURINARY SURGEON TO BELLEVUE HOSPITAL.

Whatever else we may wish to call cystitis we may start by calling it a borderline disease, somewhere between twose two illy defined territories occupied on the one hand by the endeavors of the general practitioner and on the other by the special worker in the field of genitourinary diseases. This classification of the disease, however erroneous it may be, should at least serve as a starting point of mutual interest in its consideration. Cystitis, like everything else, changes with the times. It was not so very long ago when cystitis was a very common disease. I will not go so far as to say nearly everybody had it; but I think it is safe to state that every individual suffering from painful and frequent micturition, and having pus in the urine, was put down as having cystitis. That remnants of this view of urinary ailments still exist, and in no small measure, has been my experience to observe. This then is my excuse for asking your attention to this subject, if indeed an excuse be necessary for discoursing on so misjudged an organ as the urinary bladder.

In the light of our present knowledge we may give a definition of cystitis somewhat as follows: an inflammation of the bladder, generally its mucous membrane, arising *in* the bladder and not extending *to* the bladder from other organs or structures. In the latter case it would be an extension of inflammation from some other region and have to be considered as such. The etiology of cystitis is first and foremost a lowering of the vitality of that

*Read before the Union County Medical Society of New Jersey, January 10, 1912.

viscus; exposure to cold, especially in the female, seems to effect that result. Tumors, adhesions, or abnormal positions of the pelvic organs which pull or press upon the bladder, resulting in constant congestion, stones, spinal cord lesions, and sustained distention, all weaken the resisting power of the bladder to a greater or lesser degree. A gouty or rheumatic tendency may be manifested in the mucous membrane of the bladder as in the case of any other mucous membrane. Under these or any conditions of weakened resistance, the invasion of the bladder by bacteria from whatever direction, whether through the wall of the bladder or through the urinary entrances or exit, may find a suitable soil and result in a cystitis. The *Bacillus coli* causes the largest proportion of urinary infections. The streptococcus, *Bacillus proteus Hauser*, *Bacillus tuberculosis*, *Diplococcus ureæ liquefacions*, *Streptococcus ureæ liquefacions*, *Streptobacillus anthracoides*, *gonococcus* and *Bacillus typhosus* are given as the cause of cystitis in the order named. The infection may be a mixed one. It is well always to bear in mind that the presence of bacteria alone is less likely to result in an infection of the bladder when that organ has not been previously weakened, than perhaps any other mucous membrane of the urinary tract. Its resisting power is by nature unusually fortified by its vascularity, by its activity, by scarcity of mucus glands, and by the quality of its epithelium.

Having, to the best of our present knowledge, the normal disposition of the bladder and the etiology of cystitis clearly in mind, we are in a position to consider the question of diagnosis. We may first speak of and analyze those hoary symptoms our forefathers have handed down to us as a guide to the recognition of cystitis: painful and frequent micturition and pyuria, the symptom-complex which is still a stumbling block within our midst. How easy it is when a patient with these symptoms of frequent and perhaps painful micturition and pus in the urine falls to our care to say, "here is a case of cystitis." Some of the other conditions of the urinary tract which give rise to precisely the same or modifications of the same symptoms are the following: inflammations of the male and female urethra; infections of the prostate gland; calculous disease of the urinary tract with infection; pyelitis, pyelonephritis, pyonephrosis, and renal tuberculosis. Although the bladder may participate in any extravesical process, such participation will never justify a diagnosis of cystitis, as treatment aimed at the bladder in these cases most solemnly attests. This brings one a step nearer to the diagnosis of true cystitis, by showing some of the conditions to be excluded when these time-honored symptoms are met with. This again brings one to the appreciation of another point; that when a "cystititis is not a cystitis" the diagnosis is none the less important. One step forward and one realizes that the urinary system, along with the genitalia, must be looked upon in its entirety, and that one cannot learn an easy method of diagnosis for one organ to the exclusion of the rest. When we are prepared to say the condition is a cystitis, we must be equally prepared to pass judgment upon the condition of its allied organs, otherwise the purposes of diagnosis will meet defeat in the treatment.

There is a form of cystitis quite familiar to the general practitioner. It occurs in females, old and young, with apparently normal pelvic organs, generally after a chilling. There is an abrupt onset with frequent micturition, tenesmus, and perhaps dysuria. The acid urine contains the infecting organism, usually a colon bacillus, pus, and often blood. Rest in bed, local warmth, light diet, free catharsis and some urinary sedative and antiseptic are the measures employed, and in a few days the severity of the attack subsides, and generally in two or three weeks the patients are as well as ever. Of this variety we need not deeply concern ourselves here, except so far as not to confuse it with the other and larger class of bladder infections depending on some underlying and generally chronic cause. The most important factor then in the diagnosis is seeking out this underlying cause; for, as we have mentioned, the otherwise normal bladder is not prone to entertain infecting organisms.

The routine of procedure that is essential, if we are to hope for a correct diagnosis in cystitis, is as follows:

To start with, it is necessary to obtain an hereditary and personal history, including a record of environment, habits, and metabolic tendencies; a careful estimate of the general physical condition, including the nervous system; a visual and digital examination of the external and internal genito-urinary organs, as far as this can be carried out by palpation and inspection of the abdomen and external genitalia and by digital examination per rectum and vagina. When these simple and preliminary steps have been conscientiously carried out and recorded, a vast amount of information will already have been collected. After the history and physical examination are completed, the next important thing is the study of the urinary output. Twenty-four-hour specimens and single specimens are put to the test, chemically, microscopically, and bacteriologically. Following this the more recent and refined methods of examination are employed; the catheter is used to collect urine uncontaminated by the urethra, to ascertain the presence and amount of residual urine, and to measure the bladder capacity. Then come the urethroscope, the cysto-urethroscope or the cystoscope, in case one or the other of these instruments is called upon for use. It is of some importance to know when not to use these instruments. It is more important to know what is seen when they are used. Next upon the list comes the separately collected urine by means of the ureteral catheters or bladder partition, for oftentimes it is impossible otherwise to exclude the upper urinary tract from suspicion. The estimation of renal efficiency, pyelography and the like, luckily do not concern us in our quest after a correct diagnosis of cystitis. Of the radiograph we must be ever mindful, for many a case of cystitis has lain long hidden under a stone, and that not always in the bladder. These then are the means which must be held in readiness to meet the problems of the urinary tract.

Until a shorter way is cut, this must remain the accepted road to the accurate diagnosis of cystitis. Once the diagnosis is assured, the subject of treatment holds out much promise; for with the removal of the underlying cause, which in most cases is fortunately possible, the bladder usually rights itself with an ease which is truly gratifying to see.

In closing this paper there are three points regarding cystitis which I hope to emphasize:

First: Do not depend on frequency, pain, and pyuria in making a diagnosis of cystitis, especially

if the condition shows any inclination to be a chronic one.

Second: Never be surprised when irrigations of the bladder do not cure the trouble, whatever it is.

Third: When one has reasons for believing that there is a cystitis, one should make sure of the underlying cause before thinking further of treatment.

616 Madison Avenue.

ABORTIVE TYPHOID FEVER WITH REPORT OF A CASE.

By HARRY W. LINCOLN, M.D.,

Brooklyn, N. Y.

Gastrologist to the Kings County, Swedish, and Eastern District Hospitals, Chief of Clinic Department of Diseases of the Stomach at the Polhemus Memorial Clinic.

Instances of the abortive form of typhoid fever may perhaps be sufficiently uncommon to permit of a few remarks upon the subject, with also the report of a case in which there was little doubt as to the correctness of the diagnosis. As early as 1841 Louis described a case of abortive typhoid which came to autopsy. In the Nothnagel Encyclopedia for 1901, in the classical article on typhoid fever by Heinrich Curschmann, the observations are made that splenic enlargement is quite as common as in the ordinary type of the disease, while the roseola and diarrhea are less frequently present, and meteorism is often absent. Cases with intestinal hemorrhage are mentioned. Complications and sequelæ are found as often as in cases that run their full time; and the mild cases are perhaps more often the victims of relapse than those of six or more weeks' duration. The duration of high temperature is given as not more than twelve days, and often from three to six days only. Convalescence may take place in three weeks, and periods of convalescence lasting but fourteen days occur.

Chantemesse* "found on puncture of the spleen that the splenic juice was free from the Eberth bacilli, and he explains this by assuming that in the abortive form the bacilli penetrate less deeply into the tissues."

In *American Medicine*, October 8, 1904, the following points are made in a paper upon this subject by J. B. Briggs: "The more sharp the onset, the more likely is the case to be abortive. Headache and constipation are nearly constant features. The pulse is not much disturbed. The temperature rise is sudden. The eruption is as frequent as in the ordinary type. The spleen is enlarged with ordinary frequency. The Widal reaction has been found on the third day. Complications and sequelæ are rare. Relapses are more liable to occur." Of three cases reported in the *Practitioner* of July, 1906, by Parkinson, two of the patients were constipated, and in the third patient the bowels were normal.

In an article written later, *American Journal of the Medical Sciences*, June, 1909, Warren Coleman includes under this class of cases: ambulatory; abortive; mild; typhus lævis, and typhus lævissimus. "All typhoid does not run the classical twenty-day course. The disease is of the short term variety when it lasts under three weeks. Every year patients enter Bellevue Hospital whose disease terminates in from one to three weeks. Claim was made about 1901 that paratyphoid could be differentiated by its milder and shorter course. Wunderlich stated in 1868 that no case was typhoid unless the temperature reached 103.2 F. between the fourth and sixth days. This was referred to as possessing diagnostic weight as late as 1897.* Exact methods of diagnosis have been neglected in this form of fever.

J. P. Bates cites 68 cases occurring in Panama, 21 or 32 per cent. of which were of the short duration variety. In the shortest case, lasting but eight days, the paracolon bacillus was found. Even as late as 1908 an article appeared under the title, 'Is There Such a Disease as Abortive Typhoid?' and no proof was given. Typhoid bacilli are not found in the blood as often as in ordinary typhoid."

While the above authorities agree in the main that this condition is of more frequent occurrence than is generally believed, and as is well known, that it passes often without mention or diagnosis, yet there are some points of divergence as to symptomatology and findings. It seems to be generally agreed that splenic enlargement is as frequent as in ordinary typhoid. As to the occurrence or not of the roseola, authorities whose opinions are of equal value differ. Unanimity as to the prevalence of a constipated condition of the bowels is present. On the one hand, Curschmann states that meteorism is often absent, also that complications are as likely to follow as after typhoid of the usual type, while on the other hand, Briggs thinks complications are less to be expected in the shortened form. Both, however, coincide in the belief that relapses are more prone to follow abortive than full term typhoid.

The duration of this disease as generally given is from one to three weeks. The sudden onset as above alluded to is a good point to be borne in mind. Could the Widal reaction be obtained in all cases on the third day, it would certainly be of inestimable value. As a matter of fact the average case might prove to be typhoid or any one of several diseases, as far as clinical manifestations show for the first few days. These first few days are, however, of great importance from a nursing and dietetic standpoint at least, for an extra meal or two of heavy solid food may bring about serious results even in the early stages of enteric fever. The medicinal consideration is to my mind very much a secondary one.

The reason for reporting the following case is partially at least owing to the fact that from the beginning one reaction for typhoid, namely, the Russo reaction, was always positive. This test is made by simply adding to 4 or 5 c.c. of the patient's urine 2 or 3 drops of a ½ per cent. alkaline solution of methylene blue, when, if typhoid be present, there will appear a most beautiful emerald green color of the contents of the test tube.

The patient was a male, aged 27 years, married, a man of exceptionally good physique, never having had any serious illness, and whose family history was negative as to syphilis, tuberculosis, carcinoma, etc. His occupation was an indoor one in a banking house. His temperament was perhaps a trifle nervous. He ate rapidly and in goodly amount, and slept well, and the bowels were regular. On December 19, 1911, there came on a feeling of slight malaise, with some dull headache, of which little was thought for the reason that there had been for some time periodic headache due to eyestrain.

*"Traité de Médecine," page 771. *Semaine Médicale*, November, 1889.

*Dreschfeld, Allbutt and Rolleston, "System of Medicine," article typhoid fever.

On December 20 I was called and at 4 P.M. found the temperature 103°, and the patient complaining of having had creeping chills, headache, thirst, aches in the back and legs, occasional cough without expectoration, symptoms of a coryza, etc., and a tentative diagnosis of grippe was made. December 21, in the morning, the temperature was 101°, headache was the same, the other symptoms were greatly diminished, the tongue was clean and fairly moist, the chest negative, and the abdomen was also negative as to anything which might suggest typhoid fever. There was never any roseola at any time, and it was most diligently looked for. That evening the temperature again rose to 103°, but no further discomfort developed. There was a good appetite, and no distress of any sort after taking nourishment. In fact, at any time after the first twenty-four hours the patient would have gotten up had permission been given. A rigid liquid diet given in small quantities was prescribed from the first. December 22, in the morning, the temperature was 101°, nothing of moment occurring, and in the evening it was 102.4°. The spleen was not palpable, there was no meteorism, and no diarrhea, constipation being markedly present from the beginning. The temperature record was as follows: December 23, A.M., 101°; P.M., 102°. December 24, A.M., 101°; P.M., 102.4°. December 25, A.M., 100°; P.M., 101.6°; midnight, 101.4°. December 26, A.M., 99.8°; P.M., 100.8°. December 27, the eighth day, A.M., 99.2°, and at 11 A.M., same day, the temperature struck normal and never again rose even to 99°. The pulse was at no time above 88 and most of the time was from 72 to 80. The respirations never exceeded 28, and most of the time were at 20.

From the first the Russo test was positive. A diazo test made on the 25th was negative, and a Widal made on the 26th was "incomplete." Dr. Henry Fisher, pathologist to the Norwegian Hospital, who was kind enough to make the diazo and Widal tests, took the trouble to make a culture from the urine, with the result that we were rewarded by finding numerous and active typhoid bacilli. December 28, a second diazo and also a second Widal were done, the report coming back that there were still present a few very much less active bacilli, and that the Widal was negative. This, as will be seen, was at the time when the temperature began to come down. There was for a day or so following the temperature drop a subnormal temperature of 1/5 of a degree.

The points of interest in this case may be summarized as follows: (1) the sudden onset; (2) absolute absence of all symptoms except slight headache (frontal and occipital), after the first 24 hours; (3) no spleen palpable, no meteorism, no abdominal tenderness or discomfort; (4) bowels constipated throughout; (5) no roseola; (6) no nose bleed; (7) no prostration; (8) good appetite and clear tongue at all times; (9) December 19, 1911, first complaint by the patient; January 8, 1912, patient back at his office in New York; (10) during the entire illness there was not a single gastro-intestinal symptom to be elicited from the patient. Without the positive "Russo" reaction to suggest further investigation, and the urine culture which rewarded such investigation, the case would perhaps have gone on to recovery without diagnosis. Up to the date of preparation of this report the patient has had no relapse.

113 Hancock Street.

Chronic Mediastinitis Inferior in Children.—Hutinel states that in a case of circulatory disturbance involving the vena cava, one should study the heart of the patient, make use of radiography, and notice whether the apex of the heart retracts with the systole or remains motionless. In case of immobility one should search for a mediastinitis inferior. In the latter there are various gradations from slight adhesions to adhesions so dense and so extended that heart, lungs, and liver are all involved and rendered inactive. These cases are generally due to tuberculosis, syphilis, or a combination of both. They may begin with a pericarditis, followed by a pleurisy, or the pleurisy may be the first factor. When the formation of fibrous tissue extends downward into the abdomen the liver is involved and the portal circulation is interfered with. Inferior mediastinitis is more frequent and more interesting than the superior variety. In the most marked forms there is a voluminous mass of connective tissue involving the thoracic and also the abdominal organs, including the stomach, liver, and spleen. Mediastinitis may begin with inflammation of the glands, pleurisy, or pericarditis. It comes on insidiously: the symptoms are dyspnea, circulatory disturbances, cyanosis of the lips, coldness of the extremities from compression of the abdominal aorta, edema of the legs, tachycardia, and finally asystole. The urine is small in amount, highly colored, rich in uric acid, and urobilin and contains a variable quantity of albumin or sugar, showing involvement of the pancreas. The veins of the abdomen are enlarged and there are ascites, hemorrhages from the nose and intestines, and purpura. Auscultation shows tachycardia, fetal rhythm, gallop rhythm, etc., in pronounced cases. There is an undulation of the chest walls with every beat. The lungs are congested and there are pleural adhesions. Radioscopy shows the heart increased in size and surrounded by an obscure band of connective tissue. The treatment of these cases is not simply symptomatic, but should include the treatment of the underlying disease, tuberculosis or syphilis.—*Le Bulletin Médical.*

Treatment of Suppurating Adenitis with Resorcin.—G. Fionito states that in army and navy work it is very frequent to find cases of suppurating glands, especially in the groin. In these cases it is not desirable to operate in such a way as to place the patient in the hospital with a long period of absence from duty, while a tedious granulation goes on. Most of these suppurations are due to gonorrhea or syphilis. In seeking a means of treatment which allows the patient to remain about, the author tried the use of resorcin, swabbed into the cavity of the abscess after removal of the pus through a small incision. The advantages of this method of treatment are these: the treatment lasts from six to ten days only; the esthetic results are excellent, there being little scarring; the results are of the best in streptococcic infections; the temperature rapidly falls; a large collection of pus does not contraindicate this method of treatment.—*Annali di Medicine Navale e Coloniale.*

Forms of Vertebral Rheumatism.—F. Regnault describes two forms of rheumatic disease of the spine, the osteophytic and the rheumatoid. In the first form there is an overgrowth of bony osteophytes which causes ankylosis of the bones of the spinal column, since the osteophytes overlap the intervertebral cartilages. The articular apophyses are deformed and bony growths cause intense pain through pressure on the spinal nerves. This condition is common in adult and advanced life. Deforming rheumatism causes a kyphosis of a uniform but irregular arc. The articular ankylosis comes from ossification of the interspinous and supraspinous ligaments. The articular ligaments of the apophyses especially are ossified. Horses have the same forms of rheumatism that are seen in man. —*Progrès Médical.*

New York, March 30, 1912.

MODERN VIEWS ON THE FREQUENCY AND MANIFESTATIONS OF TUBERCULOSIS IN CHILDHOOD.

ONE of the most important conclusions reached at the sixth International Tuberculosis Congress was that the campaign for the prevention of tuberculosis should begin with the earliest years of childhood. The autopsy room has shown that tuberculous lesions are present in a large proportion of children dying from various causes. Cautley of London notes the presence of these lesions in 14 per cent. of 127 autopsies on children under one year, which percentage is identical with that observed by Holt in 319 autopsies. The largest series of cases was that reported by Froebelius of St. Petersburg, who found tuberculosis in 4 per cent. of 18,540 infants dying between one and four months of age.

Recent clinical experience has shown that tuberculous infection when it occurs in the nursling is more intense though not so common as in later childhood. According to Römer (*Beiträge zur klinik der Tuberkulose*, Vol. 17, No. 3) this greater virulence of early infection is to be attributed to the fact that the young organism has not yet acquired a resistance sufficient to enable it to cope with the disease, and not so much to the fact that the "virginal" cells have an innate susceptibility to tuberculosis. Preisich, in the *Wiener medizinische Wochenschrift*, 1911, Nos. 4 and 5, points out that the varying behavior of tuberculosis during the different periods of childhood is to be explained on the basis of the mode of infection.

Thus in the nursling the infection is a massive one, occurring by ingestion and inhalation from close contact with the tuberculous parent or nurse. In later childhood and up to the school age the contact is not so intimate, and the infection in this instance comes rather from the dirt which the child takes up from the floor; this filth contains fewer microorganisms, but these are more widely distributed. This fact closely fits in with the observation made by Cautley ("The Diseases of Infants and Children," 1910) that in children tuberculosis increases in frequency but diminishes in severity as age advances. Preisich notes that from the second to the seventh year of life there is an increasing frequency of bone and gland tuberculosis, which is a more benign form of the disease. This observer also refers to a third period of tuberculosis incidence during childhood, namely, the school age. During this period the infection is mainly one by inhalation.

The frequency of tuberculosis among school children is a subject about which there has been considerable difference of opinion. F. Steinhaus (*Centralblatt für allgemeine Gesundheitspflege*, Vol. 29, Nos. 1 and 2) found evidences of tuberculous infection in 50 per cent. of these children, while F. Hamburger (*Wiener medizinische Wochenschrift*, Vol. 50, No. 25) found this percentage as high as 90 per cent. in children between from twelve to thirteen years of age in the Vienna schools. These, of course, were almost exclusively cases of latent infection as revealed by the various tuberculin reactions, and were cited as furnishing adequate support to Behring's striking hypothesis that the tuberculosis of adult life is but the recurrence of an infection acquired during childhood and remaining latent chiefly in the tracheobronchial lymph nodes.

That this latent infection gradually increases with the advancing school age is shown by the investigations of H. Nothmann (*Berliner klinische Wochenschrift*, Vol. 47, No. 9) who found that of children between the ages of three and seventeen years there were 77 per cent. who gave evidence of latent infection, but that between the ages of fifteen and seventeen years 100 per cent. gave a positive reaction. In opposition to these findings may be mentioned the views of E. Squire (*Lancet*, August 6, 1910), who, on the basis of the physical examination of school children and of clinical observations, as well as of his belief that the tuberculin reactions are unreliable, doubted that tuberculosis is common among school children. At any rate, J. Hawes (*Boston Medical and Surgical Journal*, Vol. 163, No. 24) has pointed out that there are in the schools a great many poorly nourished, anemic children who later become victims of tuberculosis.

In a most illuminating paper on intrathoracic tuberculosis in infancy L. C. Ager (*American Journal of Obstetrics and Diseases of Women and Children*, February, 1912) emphasizes the importance of making a diagnosis of tuberculosis of the various lymph nodes, which infection almost always precedes the advent of pulmonary involvement. During the prepulmonary stage of the disease, provided proper treatment is carried out, the prognosis is excellent. When manifest pulmonary lesions are present the prognosis depends upon the age of the child: during the first three years of life the prognosis is bad, but from the fourth to the tenth year, according to Ager, the prognosis, even in moderately advanced cases is more favorable than at any other time of life, provided, however, that the treatment is properly carried out. From the tenth to the fourteenth year there is a higher mortality, more pronounced in girls than in boys, which is attributed to the stress of development at the time of puberty. During this period the mortality among girls is three times as great as it is among boys.

PATHOLOGICAL HEREDITY

The past lies upon the present like a dead giant's body, so that it is as if a young giant were compelled to waste all his strength in carrying about the corpse of an old, an atavistic giant. We sleep in dead men's houses; we are sick of dead men's diseases; we live in dead men's lives. "The House of the Seven Gables," from which the above ideas are transcribed, was the product of Hawthorne's day and generation, when heredity was held more than it is now to determine human destinies. We, in the present, are apt to underrate the influence of heredity and to lay more stress upon environment and post-natal functioning, in the evolution of pathological conditions. Yet no one among us would deny a vicious heredity at least some baneful influence.

J. Grasset of Montpellier, who wrote the important work on the Half-Mad (*Les demi fous*), has in Part III of "Traité Élementaire de Physiopathologie Clinique," presented an excellent summary of the most recent ideas regarding pathological heredity. In normal life heredity is the transmission of the type of the species, the organs, temperament, physical characteristics, and analogies of family and race. In its pathological aspect heredity is the transmission of certain maladies, of predisposition to them, of refractory conditions, of malformations, and functional weaknesses; the transmission, however, being not always of the precise entities in the transmutations. Variations are introduced according to family and individual propensities; previous generations intervene also (atavism).

Heredity is not fatal or unavoidable, and its effects may be corrected, first of all by crossing. The mother's heredity and that of her family can in one way and another modify that of the father; and there can be conjoined the advantages of scientific selection, and the avoidance of the dangers of consanguinity and of the superposition of wrong heredities. Parents transmit certain acquired characters, physiological or pathological, under one form or another; thus rests upon them, therefore, the responsibility of the heredity that they transmit to their children; their vices and self-poisonings (as by alcohol) are not baneful to themselves alone. Here general hygienic deduction should have at least some deterrent effect. Yet even in children handicapped by heredity, much can be done by instruction, hygienic measures, and the inculcation of morals. The physician who must advise in such matters should be intimate with the laws of heredity, from the viewpoints both of prophylaxis and of therapy, as well as from those of pathology and pathogeny.

What is transmitted in the egg and the spermatozoön are the force, the energy, and the vitality, together with the directive idea of the species. The continuity of the individual is not incompatible with the continued renewal (birth and death) of the matter of which he is composed; nor is the continuance of the species incompatible with the birth and death of individuals. The matter transmitted by heredity serves as the vehicle of the force and energy. "The phylogenic energy that is transmitted by heredity from one individual to another, like the ontogenic energy within the individual himself, is a cellular element." Heredity is the agent of defense of the species, and within the latter are transmitted the means of this defense, whether natural or acquired. These means, like the functions of individual defense, are not the result of a preestablished finality, but are the consequence of conditions arising in the struggle for existence, realized in previous generations. The surviving species are victorious and well armed, and transmit to their descendants these antixenic properties. For the individual and species alike the outcome of the struggle is not always fortunate. Heredity transmits maladies, malformations, infirmities; if such alteration is pronounced enough to menace the persistence of the type or to modify it seriously, heredity will in the end obliterate the type.

Life in its essence is not characterized by birth, evolution, and death; the problems of the beginning and the end of life are inaccessible to the biologist. Life, to the student of biology, "continues itself indefinitely by reproduction through successive individuals despite the death of these individuals, always comparable to itself in the same species, defending itself against the enemy and against the movement of change or destruction by means of heredity, which is the great antixenic function of the species."

NATURE OF HYSTERIA.

Despite the uniform advance of medicine during the more recent decades we seem to be as far as ever from a satisfactory conception of hysteria so called. Not only do affect syndromes common to hysterics occur at times in sound objects, but even the stigmata believed to characterize the disease are sometimes seen in subjects who never develop hysterical outbreaks even under due provocation. Moreover, all kinds of static and dynamic expressions of hysteria may be encountered in psychoses and psychoneuroses, so that they seem bound up, not with hysteria *per se*, but with the degenerative neuropathic substratum in general.

At a recent session of the Gesellschaft fur Natur- und Heilkunde zu Dresden (*Münchener medizinische Wochenschrift*, January 2) there was a sort of symposium on this subject. Ganser came out strongly against the conception that hysteria is a disease *per se*. For him it represents a substratum which is widely present but usually latent until placed in evidence by an aggregation of factors in which age, race, sex, and temperament play a rôle, along with special predisposing and exciting causes. Stegmann reviewed the teachings of Freud, which he stated to be insusceptible of demonstration in a short compass. This is the commonest objection on the part of physicians, who must always ask if the results to be obtained justify the unwieldy technique and prolonged application required. No one denies that Freud's work has indirectly proved of great benefit by arousing attention and provoking discussion.

Weisswange covered the subject of the relation of hysteria to the female generative organs, which involves perplexing and complicated problems. Dis-

eased adnexa and uteri are often responsible for general nervousness, which is by no means to be carelessly called hysteria. That the closest relations exist between the female psyche and the sexual organs must be admitted. The latter should by all means receive proper treatment, but so far is surgical intervention from being specially indicated that the danger of a malpractice suit must always be borne in mind; it being well known that, for whatever reason, suits of this kind are frequently instituted by hysterical women who have submitted to operation. Haenel, who covered traumatic hysteria, describes no less than five categories under which victims of this affection fall, depending on the nature of the injury, time intervening, presence of predisposition, influence of suggestion, motive for simulation, etc. An immediate causal connection between an accident and hysterical developments of a permanent character without the intervention of some other element is doubtless rare.

FRESH AIR IN SCHOOLS AND HOSPITALS.

The subject of ventilation is very much in the scientific and public mind at the present time, though there is by no means unanimity as to the best way of effecting it. Leonard Hill has recently advanced certain iconoclastic views on ventilation, boldly holding that the chemical purity of the air in a room or building is of minor consequence and that the main factors in ventilation are the movement of the air and the maintenance of a sufficient degree of humidity. The reason why a current of air coming through an open window has so refreshing an effect is because of stimulation of the cutaneous nerves. Probably this opinion unduly depreciates the healthfulness of chemically or relatively pure air and exaggerates the good effects of air in motion, but undoubtedly both are important factors in the maintenance of health.

At the meeting of the American Climatological Association held in Montreal, June, 1911, Brannan stated that for the past two years the artificial system of ventilation has been abandoned at Bellevue and its three allied hospitals, and that the air in the wards has been kept sweet and pure by means of open transoms and windows. There is but little complaint of draughts, though the patients are all accustomed to the stuffy air of their tenement homes. The temperature of the wards is kept below 65° F. in the winter, varying from 62° to 65° F. during the day and in the neighborhood of 60° F. or below at night. In the new Bellevue Hospital every ward is provided with a commodious balcony, and all the buildings have roof gardens.

The inauguration and extension of open-air schools have already conclusively demonstrated their value in the case of anemic and tuberculous children and of those predisposed to tuberculosis. In order to preach successfully the gospel of health in cities too great stress cannot be laid on the absolute need of abundant fresh air for children. The custom of overheating buildings, offices, and homes is an important factor in increasing susceptibilty to colds and may possibly partly account for the prevalence of pneumonia in the colder countries.

THE TRIUMPH OF AMERICAN MEDICINE IN THE CONSTRUCTION OF THE PANAMA CANAL.

The Panama Canal when completed bids fair to prove a triumph from several points of view. The greatest triumph, however, in connection with its construction is that it was rendered possible to construct it at all. The French endeavors in this direction were made futile by climatic conditions. The region in and about Panama was a perfect pest hole, reeking with tropical diseases, over which the ubiquitous mosquito reigned supreme. It was freely predicted that the obstacles raised by tropical conditions in their most accentuated stage of development would be hard to overcome, if not insuperable. If Colonel Gorgas and his staff had not been able to banish disease from the Canal Zone the making of the canal would doubtless have been again abandoned. As it is, a complete and signal victory has been gained by medical sanitary science, and the canal has been built under more healthy conditions than usually prevail in temperate climes. Indeed the Canal Zone is in process of developing into a health resort. All this has recently been again well set down (it cannot be done too often) in a small book written by Dr. J. Ewing Mears of Philadelphia entitled "The Triumph of American Medicine in the Construction of the Panama Canal."

News of the Week.

Health of the Canal Zone.—For the month of January, 1912, the Department of Sanitation of the Isthmian Canal Commission reports among employees, 21 deaths from disease and 14 from violence, a total of 35, giving an annual average death rate for the month of 8.10, as compared with 10.14 and 10.57 for the same month in 1911 and 1910. The deaths from the principal diseases were as follows: Chronic nephritis, 3; hemoglobinuric fever, 1; lobar pneumonia, 3; malaria, 1; tuberculosis, 3; typhoid fever, 1. Including both employees and civil population, the death rate for the month was 17.67, as compared to 21.05 for 1911 and 21.26 for 1910. No cases of yellow fever, smallpox or plague originated on the Isthmus during the month. One case of yellow fever was removed from a vessel arriving from Guayaquil and isolated at Culebra Island quarantine station.

Home Tuberculosis Hospital.—In the attempt to wipe out centers of tuberculosis infection in tenement districts, the New York Association for Improving the Condition of the Poor is trying the experiment of leasing a section of the East River homes, or Vanderbilt tenements, which will be converted into a home hospital. Into each of the twenty-four apartments will be moved a family which has been dependent upon the association because of tuberculosis, and an effort will be made to determine whether the spread of the disease can be checked and cures effected under medical direction, aided by good nursing, adequate relief, freedom from worry, fresh air, and sunshine. A hospital and sanatorium régime will be strictly enforced. After dismissal each family will be moved into a suitable home and supervision continued. Of 3,500 families now under the care of the association, there are 284 in which there are one or more cases of tuberculosis. In fifteen of these both parents and one or more of the children are diseased.

Course in Surgery.—A practical course in the progress of general surgery will be given in the

Academy for Practical Medicine at Dusseldorf, Germany, from April 15 to 27, 1912, by Prof. Dr. Witzel, Prof. Dr. Lmiger, Dr. Janssen, and Dr. Graf, with a number of clinical demonstrations by well-known surgeons on a variety of subjects, including the treatment of fractures, of hernia, of surgical tuberculosis, of liver abscess, of spinal disease in children, and of appendicitis and colitis. Complete programs can be obtained from the secretary of the Academy. No charge is made for attendance.

Dr. Dexter D. Ashley of New York lectured before the Waterbury, Conn., Medical Association on March 11, on "The Abbott Treatment of Fixed Lateral Curvature."

Dr. J. Whitridge Williams of Baltimore will read a paper entitled, "What can be done to improve the teaching of obstetrics in this country?" at a meeting of the Section of Obstetrics and Gynecology of the New York Academy of Medicine on Thursday evening, April 12. Dr. W. M. Polk, Dr. E. B. Cragin, Dr. J. C. Edgar, Dr. J. W. Markoe, and Dr. Austin Flint, Jr., will participate in the discussion.

The City's Health.—For the week ending March 23, the death rate in New York was 10.15, or almost one point lower than the same week in 1911. The total number of deaths was 1,602, the principal causes being heart disease, 215; pulmonary tuberculosis, 208; lobar pneumonia, 162; bronchopneumonia, 135; diarrheal diseases, 105; diphtheria and croup, 30; scarlet fever, 22, and measles, 14. For the first eleven weeks of 1912 the death rate was 15.63 per 1,000, as against 16.67 for the corresponding weeks of 1911.

The Warren Triennial Prize was founded by the late Dr. J. Mason Warren in memory of his father, and his will provides that the accumulated interest of the fund shall be awarded every three years to the best dissertation considered worthy of a premium, on some subject in Physiology, Surgery, or Pathological Anatomy; the arbitrators being the physicians and surgeons of the Massachusetts General Hospital. The subject for competition for the year 1913 is on "Some Special Subject in Physiology, Surgery, or Pathology." The dissertation must be in either the English, French, or German language, and must be typewritten and suitably bound, so as to be easily handled. Work that has been published previously will not be considered in competition. The name of the writer must be enclosed in a sealed envelope, on which must be written a motto corresponding with one on the accompanying dissertation. The amount of the prize for the year 1913 will be $500. In case no dissertation is considered sufficiently meritorious, no award will be made. Dissertations addressed to the Resident Physician, Massachusetts General Hospital, Boston, will be received until April 14, 1913. A high value will be placed on original work.

New Beth Israel Hospital.—The directors of the hospital have voted to acquire a new site for the hospital and to proceed as rapidly as possible with the erection of the building, for all of which it is estimated that an expenditure of one million dollars will be required. The present hospital quarters are quite inadequate for the accommodation of all those applying for treatment.

Quarantined for Beriberi.—With two members of its crew dead from beriberi, and six others ill with the disease, the British bark *Brilliant*, which sailed from Bombay three months ago, reached the Philadelphia quarantine station on March 17, and for some unexplained reason was detained there. The sick men were removed to a hospital for treatment.

Dr. George A. Soper, head of the Metropolitan Sewerage Commission, told a large audience at Columbia University on March 18 of the dangers resulting from the contamination of the Hudson and East Rivers with the sewerage from New York and adjacent towns.

Charitable Gifts.—The Presbyterian Hospital, New York, receives $15,000 by the will of the late Mrs. Cornelia Eaton, to be used in establishing three free beds to be known as the Dr. Reuben S. Carpentier Memorial. St. Vincent's Hospital, New York, is also remembered, receiving a portion of the residuary estate on the death of the testatrix's husband. By the will of the late Mrs. Mary L. Laurence, Seton Hospital receives $10,000. The Tuberculosis Preventorium has recently received a gift of $5,000 from Mr. J. P. Morgan. By the will of the late Rear Admiral George W. Melville, of Philadelphia, the sum of $5,000 is bequeathed to the Mt. Sinai Hospital and the Presbyterian Hospital, each for the endowment of free beds in memory of his wife, and to be known as the Esther Polis Melville beds.

Centenary of the Academy of the Natural Sciences of Philadelphia.—The hundredth anniversary of the founding of the Academy of the Natural Sciences was celebrated formally at Philadelphia by a three days' session from March 19 to 21, under the presidency of Dr. Samuel G. Dixon, Commissioner of Public Health of the State of Pennsylvania. There were present as delegates representatives of leading colleges and universities and of many foreign and American learned societies. The session was opened on the evening of March 19 when, after an address of welcome by Mayor Blankenburg, Dr. Dixon delivered the Annual Address of the President. A number of interesting papers were read on March 20 and 21, and on the evening of the 20th a reception was tendered the members and visiting guests by Dr. and Mrs. Dixon and Miss Dixon. A banquet was held on the evening of the 21st, and it was attended by many distinguished persons in public and scientific life.

Dr. Wiley Says Drug Manufacturers Are "Dopers."—In a speech before the Pure Food Board, Dr. Harvey W. Wiley, formerly chief chemist of the Department of Agriculture, bitterly opposed the removal of the skull and cross-bone sign from packages containing poison and urged the adoption of a proposed new regulation covering the sale of poisonous drugs, providing for keeping a record of them from their manufacture or importation until they are finally used. Dr. Wiley aroused the ire of the representatives of the drug associations by referring to the drug interests as "dopers."

Famine in Russia and China.—Recent reports from Russia indicate that the famine in the eastern portions is of serious proportions, some thirty millions of people being affected. In China conditions have also grown worse instead of better, and the New York China Famine Relief Committee estimates that one million dollars will be needed to extend relief over the whole famine area.

To Head State Institutions.—Gov. Dix of New York sent to the Senate on March 22, for confirmation, the following nominations of managers and trustees of State institutions: *Craig Colony for Epileptics.*—Dr. Frederick Peterson, New York; Mr.

A. I. Dow, New York. *Buffalo Hospital.* William A. Douglas, Buffalo. *Hospital for Crippled and Deformed Children.* Mr. Frank M. McMurry, Yonkers. *Hudson River Hospital.* Mr. W. B. Dinsmore, Staatsburg. *St. Lawrence Hospital.* Mr. M. C. Ransome, Malone. *Binghamton Hospital.* Mr. H. A. Stephens, Binghamton. *Raybrook Sanatorium for Incipient Tuberculosis.* Dr. Charles Stover of Amsterdam.

Health Board and Building Inspection. In Sacramento, Cal., the Health Board has been given authority over the building inspectors and the electric light inspectors, who will now report directly to the Board. The Health Department of Sacramento is responsible for the sanitary condition and safe construction of buildings so far as concerns the public safety, and the recent passage of a tenement house law has thrown upon the department a large amount of work which it was unable to perform without expert assistance. The entire construction of a building will now be under the supervision of one responsible bureau.

Class Reunion.—The Class of 1892, of the Medical Department of the University of the City of New York, will hold a reunion and banquet at the Hotel Martinique on Wednesday evening, April 3, 1912. All members of the class are invited to attend. The committee in charge include Dr. J. Emmet Tower, Dr. John F. Hagerty, Dr. John S. Stetson, Dr. George B. Campbell, and Dr. Robert E. Coughlin.

Model Tenements in Rochester.—Plans are being prepared for the erection of a block of model tenement buildings in Rochester, N. Y., similar to those already open in New York. Mr. George Eastman of the Eastman Kodak Company is financing the enterprise, which it is estimated will require an investment of about one million dollars.

Health Officers to Meet.—The sixth sanitary conference of the health officers of Connecticut will be held at Hartford on April 3. Dr. H. O. Averill, State commissioner on domestic animals, and Professor H. W. Conn, State bacteriologist, will discuss the subject, "Co-operation between health officers and the commissioner on domestic animals for the suppression of glanders and rabies." The medical inspection of schools, the protection of water supplies, and other public questions of interest will also be discussed.

Ellis Island Inspected.—Surgeon-General Blue of the United States Public Health and Marine Hospital Service, paid an official visit to Ellis Island, New York, on March 22, and again on March 26, for purposes of inspection. He was accompanied by the Commissioner of Immigration, and commented on the improvements during the last decade in the manner of handling immigrants, but thought an increase in the medical staff desirable.

Smallpox Scare.—An outbreak of smallpox in Willimantic, Conn., has caused general alarm throughout the town and neighboring places. The city officials are active in attempting to control the situation, and the closing of the mills has been suggested. The health authorities of the city of New London have ordered the railroad companies not to carry passengers through from Willimantic to New London, and similar steps may be taken by other adjacent towns.

Insane Aliens.—The New York State Lunacy Commission in a recent report to Governor Dix urges the desirability of a change in the immigration laws so that the deportation of insane aliens may be easier, and the overcrowding in the State hospitals reduced. The insane population is steadily increasing, and it is estimated that there are at least 8,000 insane aliens now being cared for in State institutions at great cost, and to the detriment of the native born.

Civil Service Examination.—On April 20, 1912, the New York State Civil Service Commission will hold an examination for the purpose of filling a vacancy in the position of optical surgeon at the State Agricultural School, Industry. The employment is for only one day a week, and the salary $480 a year.

Tricounty (Mississippi) Medical Association.—Under this name the physicians of George, Green, and Perry Counties, Mississippi, organized recently. Officers were elected as follows: *President*, Dr. W. D. Ralliff, Lucedale; *Secretary-Treasurer*, Dr. J. E. Green, McLain. Meetings will be held at Lucedale on the second Tuesday of each month.

Medical Library Club.—The physicians of Kansas City, Mo., have recently formed an organization to be known as the Kansas City Medical Library Club, its object being to obtain for its members an extensive library of medical books and periodicals. Dr. R. M. Schauffler is the president of the club, and Dr. Rush E. Castelaw the secretary and treasurer.

The Florida State Medical Association will meet in Tampa on May 8.

The Alabama State Medical Association will hold its annual convention in Birmingham on April 16-19. The annual address by the monitor of the association, Dr. S. W. Welsh of Talladega, will be delivered on the evening of April 17.

Health Conferences.—Dr. E. Dana Durand, director of the census, will address the health conference which will be held in Nashville, Tenn., in connection with the Southern Commercial Congress, April 8 to 10, on the importance of vital statistics. Dr. Oscar Dowling of Louisiana will serve as presiding officer of the conference. The State directors of sanitation will also hold a conference in Nashville on April 2, 3, and 4, as a part of the Southern Educational Conference.

The Medical College of Georgia, at Augusta, has become the medical department of the University of Georgia. The act of the Legislature authorizing this move was passed last summer, and the formal transfer of the property of the medical school to the University trustees was made on March 6.

The Committee on Public Instruction in Medical Matters of the Medical Society of the District of Columbia, recently appointed, is fulfilling its function by publishing in the Sunday papers a short statement on personal hygiene, in which novelty is subordinated to accuracy, and sensationalism to practicalness. When opportunity offers a word is said regarding the functions and aims of the medical profession. In addition, a public lecture is being given every two weeks at present with the same object.

The Galesburg, Ill., Medical Society, at a meeting held March 7, elected the following officers: *President*, Dr. C. E. Quaife; *Secretary*, Dr. E. N. Nash.

Obituary Notes.—Rear-Admiral James Rufus Tryon, ex-medical director of the United States Navy, a graduate of Union College and of the University of Pennsylvania, Department of Medicine, in 1861, died at the United States Naval Hospital

in Brooklyn, New York, on March 20, aged 74 years. Admiral Tryon entered the navy as an assistant surgeon in 1863, and served in the West Gulf Squadron through the war, being present at the battle of Mobile Bay. After some years of shore duty he was in 1870 assigned to the Atlantic Fleet and worked in Yokohama during the smallpox epidemic of 1871. In 1893 he became Surgeon-General of the Navy, and in 1899 retired from active service. He was for six years in charge of the hospital at Sailors' Snug Harbor.

Dr. Thomas H. Montgomery died at Philadelphia on March 20 at the age of 30 years. He was a member of the class of 1893 College of the University of Pennsylvania, but he received his Ph.D. degree from the University of Berlin in 1894 after three years' study in zoology. On returning to this country he held a research position in the Wistar Institute of Anatomy for several years. He was also professor of biology and Director of the Museum of the Wagner Institute. In 1898 he was made instructor and at a later date assistant professor of zoology in the University of Pennsylvania. From 1903 to 1908 he was professor of zoology in the University of Texas. Subsequently he became professor of zoology in the University of Pennsylvania. Dr. Montgomery was an investigator of the first rank and he was the author of numerous treatises on the anatomy of certain worms, rotifers and insects, on the classification and habits of birds and spiders, on comparative studies of cells, on the maturation of germ-cells, and on the principles of phylogeny. He was the author of "The Analysis of Racial Descent in Animals." He contributed many and notable discoveries as to the structure and history of germ-cells.

Dr. Julius Lincoln Salinger died suddenly on March 25 at Philadelphia while giving testimony as a witness in court, at the age of 45 years. He was graduated from Jefferson Medical College in the class of 1886 and he was at one time assistant professor of clinical medicine in his alma mater and chief clinical assistant in the medical dispensary of Jefferson Hospital and visiting physician to the Philadelphia General Hospital. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, and the American Medical Association. He was editor of the American translation of Modern Clinical Medicine.

Dr. Edmund K. Goldsborough of Washington, D. C., died on March 14 at the age of 69 years. He was a graduate of the Medical College of Virginia, at Richmond, and served as surgeon in the Confederate Army during the Civil War.

Dr. William Rouse died at McKinley, Pa., on March 11, at the age of 27 years. He was graduated from Jefferson Medical College in the class of 1909.

Dr. A. H. R. Guiley died at Easton, Pa., on March 11, at the age of 56 years. He was graduated from Jefferson Medical College in the class of 1877, and was a member of the Easton Board of Health.

Dr. Frederick Castalucci died at Rosetto, Pa., on March 11, while on a visit, at the age of 29 years. He was graduated from the medical department of the University of Colorado.

Dr. A. M. Headley of Rio Grande City, Texas, died February 27, at the age of 76 years. He was born in England and after receiving his medical education entered the British navy as surgeon. When the Civil War broke out he came to this country and became a surgeon in the Confederate Army. At the close of the war he went with a number of ex-Confederate officers to Mexico to join the army of Maximilian. He did not join that army but began the practice of medicine in Vera Cruz, later going to Tampico. After some years he crossed the border and settled in Rio Grande City, which he made his home until his death.

Dr. Francis J. Stevens of Haverhill, Mass., died March 8, at the age of 88 years. He was born in Gilford, N. H., and was graduated from the Albany Medical College in 1855. He was the oldest Odd Fellow in the State and was also the only surviving charter member of the Pentucket chapter of Masons.

Dr. M. L. Shine of Winthrop, Iowa, died on March 4, of septic poisoning following a small cut received during an operation. He was a graduate of the College of Medicine of the State University of Iowa in 1887.

Dr. George W. Miller of Des Moines, Iowa, died of disease of the heart on March 6, at the age of 55 years. He was one of the oldest practitioners in that city, having settled there in 1880.

Dr. Thomas Gilully of Union Center, Wis., a graduate of the Rush Medical College of Chicago in 1871, and a member of the Wisconsin State and Juneau County Medical Societies, died suddenly on March 12, aged 72 years.

Dr. William Vincent Dee of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1893, and a member of the New York State and Kings County Medical Societies and of the Brooklyn Pathological Society, died at his home suddenly on March 18, aged 46 years.

Dr. David Thomas Bowden of Paterson, N. J., a graduate of the University of Maryland in 1889, and a member of the American Medical Association, and the New Jersey State and Passaic County Medical Societies, died at his home on March 19.

Dr. Daniel A. La Force of Ottumwa, Ia., a graduate of the College of Physicians and Surgeons of Keokuk, Iowa, in 1863, a surgeon in the United States Army during the Civil War, and a member of the Iowa State and Wapello County Medical Societies, died at his home on March 10, aged 75 years.

Dr. Hannah T. Croasdale of Philadelphia died at the home of her daughter at Syracuse, N. Y., on March 15 at the age of 77 years. She was graduated from the Woman's Medical College of Pennsylvania in the class of 1880 and was for many years professor of gynecology in her alma mater.

Dr. Edward H. Kelly of Ironwood, Mich., a graduate of the University of Michigan, Department of Medicine and Surgery, in 1869, and a member of the American Medical Association and the Michigan State and Gogebic County Medical Societies, died suddenly at his home on March 8, aged 69 years.

Dr. Meredith Walton Henry of Waelder, Tex., a graduate of the Eclectic College of Medicine of Cincinnati, Ohio, in 1857, died at his home on March 12, aged 81 years.

Dr. Frank Linsley Ives of New York, a graduate of the College of Physicians and Surgeons, New York, in 1871, and a member of the New York Academy of Medicine, the New York State and County Medical Societies, and the American Laryngological Association, died at his home on March 22, after a short illness, aged 62 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INJECTION FEVER—SALVARSAN—ALCOHOL AND MENTAL CAPACITY—CONCLUSION OF DEBATE ON EXOPHTHALMIC GOITER—OBITUARY.

LONDON, March 8, 1912.

It has long been recognized that medication by the injection method is apt to set up febrile action; so often is this the case that some practitioners speak of "injection fevers" as a group so extensive that we might in turn name it drug fever, but substances we should scarcely include as drugs are equally pyretogenic. Among them protein, sugar, salt, and even water may be named, and we accordingly hear of protein fever, salt fever, ferment fever, and tissue fever when those interested in the subject meet. Drs. E. C. Hort and W. J. Penfold propose to add salvarsan fever and have submitted a paper to that effect to the Pathological Section of the R. S. M. At first the cases in which this drug had been injected and followed by fever were looked upon as salt fever, but soon were regarded as due to bacterial infection of the solutions, and in numerous instances such infection had been proved to have been present. Further, if solutions were made with perfectly pure distilled water pyretogenic effects did not follow—a fact which seems to show that at any rate water fever has not a good claim to a place in the group. Drs. Hort and Penfold report control experiments showing that dead organisms do not cause fever but heated water or solutions containing very few will do so and this effect they attribute to a heat-stable, filter-passing molecule which may or may not be of bacterial origin. Water, bacteria-free, which had been distilled in the ordinary metal still was pyretogenic but water which had only come in contact with glass was not. They concluded that salvarsan fever was not necessarily due to micro-organisms or to unbroken bacterial protein; that the heat-stable filtrable substance was an important factor; that the sterility of a watery solution of salvarsan was no guarantee of the absence of this pyretogenic substance; the only certain method of preventing salvarsan fever was to use water freshly distilled in glass and to inject immediately. If storage was necessary for a time it must be collected in sterile glass and hermetically sealed.

In his Annual Report of the Royal Edinburgh Asylum, issued on the 27th ult., Dr. George M. Robertson says the admissions numbered 179, the exciting cause being alcoholic indulgence in 17.8 per cent. In the males 28.9 per cent., more than double the proportion in the previous year. Over 43 per cent. had had previous attacks of insanity. Influenza was absent as a cause for the first time for twenty-one years. He suggests that we may be developing an immunity, for it is prevalent if less virulent than at one time and young people are susceptible. The recovery rate for 1911 was 30 per cent. of admissions. Dr. Robertson attributes great efficacy to fresh air treatment of all mental disorders. He deprecates the too common postponement of treatment after premonitory symptoms have set in. Half the insanity that occurs between the ages of twenty and thirty, Dr. Robertson estimates as hereditary; between forty and fifty as acquired. Of the latter the majority are due to alcoholism or to general paralysis.

A different story comes from Ireland where Dr. Dawson has been studying the relations of insanity to some circumstances of life as pauperism, emigration, mortality, or criminality. In a paper at the Royal Academy of Medicine he gives his results. As to alcoholism he found there was no correspondence between the distribution of insanity and drunkenness; and in general it appeared that alcohol was of comparatively small importance as a cause of insanity in Ireland. Drunkenness, he said, was in greater excess in rural districts than in larger towns, just the opposite of what was found in England or Wales.

Extreme alcoholism was the subject of a lecture delivered at University College on February 27 by Dr. David Heron. He dealt with data as to 1,000 inebriates collected by the Inspector under the Acts (Dr. Branthwaite). He found mental defect the most important condition on admission to the Reformatory. Out of 865 females admitted only 36 per cent. were of average mental capacity when sober; 54 per cent. were defective, and 2 per cent. were certified as insane during detention. The evidence indicated that to a great extent the defective state preceded and was only very slightly increased by the alcoholism. As to the result of reformatory treatment out of 1,800 inebriates whose conduct could be traced for a limited time after discharge only 380 were doing well, less than 21 per cent. A striking feature of the investigation showed that the 865 female inebriates had 2,589 children. The 389 defectives had had 1,672. Dr. Heron said the vast bulk of cases of mental defect being inherited, the high fertility of these women was a serious social problem. The real remedy for two-thirds of existing alcoholism he held was the permanent segregation from school age of the feeble-minded child. By thus cutting off the supply of defectives at the source, the problem of extreme alcoholism, at least to the extent of two-thirds, could be solved in a generation.

The debate I have reported on exophthalmic goiter was resumed on Tuesday evening for the third time, the question of anesthesia being chiefly considered. Mr. Barker was well satisfied with local analgesia, though in certain cases he had used general anesthetics, with scopolamine and morphine in addition. Mr. C. Symonds dwelt on the differentiation of Graves' disease from cases of simple goiter in nervous patients. Mr. Armour had operated on twenty-six cases, and all but one under general anesthesia, and that one died. Mr. Walter Edmunds maintained that the mode of anesthesia should be decided on general grounds. Dr. Scharlieb held that cloroform and ether were quite safe in these cases and the liability to psychic shock was rather against the local method. Mr. Page fully agreed with this. Dr. Barton had also found general anesthesia safe, and considering the type of patients the balance of advantage was with it. Mr. R. Farrant considered that in Graves' disease there was a cycle from thyroid excess to deficiency. At the beginning he looked for excess, though often it might be slight, but it went on to insufficiency. If the hyperthyroidism were detected two or three years earlier than usual Graves' disease would soon cease to exist. Dr. Paterson held that general anesthesia was not devoid of risk. Chloroform, whether by the open method or with apparatus for measuring the dosage, he considered unjustifiable, and hospital records supported this view. Mr. B. Robinson spoke well of the intravenous method of administration. Mr. James Berry's operations num-

bered 670 for removing goiter of various forms. But he had only eleven cases of true Graves' disease in which he felt justified in operating. He had collected statistics from hospitals of ninety-seven cases and the deaths were sixteen, twelve of them within forty-eight hours. Of the survivors most were called benefited but little was known of the ultimate results. Perhaps the poor results were to be attributed to the fact that in this country the operations were not performed early enough. The condition was so distressing that the mortality was not the sole question. In true Graves' disease the operation was serious, even dangerous, most so in acute and in advanced cases in which there was degeneration of muscle, especially of the heart. Local anesthesia had the advantage that the patient could drink at once, and large quantities of fluid were most important. He objected to chloroform.

Lieut.-Col. George W. McNalty, C.B., died on March 1 in his seventy-fifth year. He qualified at the Dublin College of Surgeons in 1857 and took his Fellowship in 1868, having in the meantime graduated M.D. at St. Andrews (1862). He joined the army medical staff in 1863. During the Franco-German War he had charge of the British military ambulance at the siege of Paris and was present in several engagements for which he was awarded the German war medal and the French bronze cross. He served in the Ashanti War (1873-74) where he was in several battles and the capture of Coomassie, was mentioned in dispatches, awarded the medal and clasp, and promoted surgeon-major. In the Russo-Turkish War (1876-77) he was chief surgeon and commissioner of the National Aid Society, present at the siege of Plevna. In the Afghan War (1878-80) had part in the march from Cabul to relieve Candahar and was again mentioned in dispatches and given the medal with clasp and the bronze star. In the Egyptian expedition was in Tel-el-Kebir and again received medal with clasp and bronze star, as well as the order of Osmanieh. He retired as Brigadier Surgeon Lieut.-Col. in 1892. He was for some time honorary surgeon to the Viceroy of India and made C.B. in 1807.

Inspector-General Mahon, C.B., died on the 26th ult. after a distinguished career. Born in 1851 he qualified and entered the navy in 1878 and the next year was in the Zulu War as surgeon to the Boadicea and received the medal. In 1881, as surgeon to the Flora, he landed with the naval brigade and was in the actions of Laing's Nek and Majub Hill, and was promoted to staff surgeon for his gallant conduct. In Egypt (1882) and in Burma (1885-87) he again served with distinction. He was afterwards Deputy-Inspector General at the Royal Naval Hospital, Haslar, until 1903, when he became Inspector-General of Hospitals and Fleets. He received his C.B. in 1892.

Deputy-Surgeon-General John Sparrow, formerly of the Irish Fusiliers, died on the 1st inst. aged eighty-two. He took the M.R.C.S. in 1854 and obtained his first commission that year. Much of his time of service was spent in India. He was in the N. W. Frontier Campaign (1858) and accompanied the Peshawur expedition for which he was awarded the medal and clasp.

Dr. R. Dill, who practised many years in Brighton but had long retired, died at Burgess Hill on February 24 in his ninetieth year. He qualified M.D. and L.R.C.S., Edin., where he had been one of the students under Sir James Simpson. Dr. Stanley Elliott, late Medical Superintendent of Caterham Asylum, died on the 3d inst. at the age of sixty-eight. He was M.R.C.P. and F.R.C.S. Edin. Surgeon Major Heffernan, I.M.S., retired, died February 20 at the age of eighty-one. Surg.-Major Frank Simpson, R.A.M.C., retired, died on February 28.

THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE.

(From Our Manila Correspondent.)

HONGKONG, January 27, 1912.

THE Second Biennial Congress of the Far Eastern Association of Tropical Medicine began its sessions at Hongkong on January 20, and met daily thereafter until January 27. The Congress was unusually well attended, delegates being present from Japan, German China, Shanghai, Hongkong, Macao, Canton, Indo-China, the Straits Settlements, the Federated Malay States, India, Ceylon, Java, and the Philippine Islands. The United States Army was represented by Major Chamberlain, Major Ashburn, and Captain Vedder, the United States Navy by Surgeon Butler, and the Philippine Civil Government by Drs. Paul C. Freer, and Victor G. Heiser.

First Day.

The opening session of the Congress was held in the city hall at 11 A.M., January 20. An address of welcome was delivered by His Excellency, Sir Frederick Lugard, G.C.M.G., C.B., D.S.O., Governor of the Colony. His Excellency dealt, in a most entertaining and instructive manner, with the various phases of tropical medicine, and mentioned the experiences he had had in his many years of tropical service in Africa. He spoke in a most appreciative manner of the great work which the medical profession had rendered to assist in making the tropics healthful; not only was it possible for the white man to reside there with as much assurance against contracting disease as in the temperate zone, but the native as well had been freed from many of the diseases which heretofore had shackled him, and comforts had been made his which might never have been but for the white man's presence. He called attention to the fact that 44 per cent. of the foreign trade of the United States and the United Kingdom was with the people of the tropics, but that sanitation and medical relief had gone hand in hand with these trade relations. The delegates were most warmly welcomed, and every assurance given, so far as the Government, at least, was concerned, that all doors in the Colony for the gaining of medical knowledge would be freely open to them.

The next address was that by the president of the association, Dr. J. Mitford Atkinson, who took as his subject, "The Progress of Tropical Medicine During the Past Twenty-five Years." He dealt with the historical aspect of tropical medicine, and more especially with the wonderful change which had been made in the Colony of Hongkong by the control of malaria. At one time the abandonment of the island, on account of the ravages of malaria, had been considered seriously a number of times.

At the close of Dr. Atkinson's address the delegates were formally presented to His Excellency, the Governor. In the afternoon a garden party at the Government House was given by His Excellency, in which a large percentage of the leading citizens of Hongkong took part and extended a most cordial welcome to the delegates.

Second Day.

The first paper read was entitled, "The Substance in Rice Polishings Which Prevents Polyneuritis Gallinarum and Beriberi," by Major Chamberlain and Captain Vedder of the United States Army Board for the Study of Tropical Diseases, was ready by Dr. Vedder. This paper dealt with a large series of experiments which had been made with a view of determining the exact nature of the substance which is contained in the outer portion of the rice grain, which is capable of preventing beriberi in man, and polyneuritis in fowls. These officers have carried the work somewhat further than was done by Frazer and Stanton, and by the means of alcohol were able to extract from rice polishings a substance which, in definite and measurable amounts, is capable of curing polyneuritis in fowls. So far analysis has not revealed the exact nature of this substance. The extract has, however, been used in the treatment of fifteen undoubted cases of so-called infantile beriberi, in Manila, with complete success. Further experiments are being made.

The next paper was entitled "Beriberi," by Dr. C. Noel Davis of Shanghai. In this the author related a series of instances in connection with prisoners at the municipal jail in Shanghai, in which the diet factor was of undoubted importance in outbreaks of beriberi, but he felt that the so-called rice theory, as now understood, did not explain all cases, and for this reason he made further experiments. His review of the literature convinced him that beriberi was associated with insanitary habitations, which caused him to think that the disease must be of an infectious nature, and that bedbugs might be concerned in its transmission. He reported a number of cases in which bedbugs were permitted to feed upon patients who were ill with beriberi, and then to bite persons who were free from this disease. After making a number of experiements in which the time of placing the bug upon the well persons varied from a few hours to several days, he claims that he was finally able to induce the disease in two cases.

In the discussion which followed the fact was brought out that not sufficient evidence was adduced to show that the dietary factor in these cases had been entirely eliminated.

The next paper, entitled "Beriberi, with a Suggestion for Governmental Aid in Its Eradication," was read by Dr. Victor G. Heiser. In this paper the author stated that, for practical purposes, he considered it as proven that beriberi undoubtedly occurred in individuals whose staple article of diet was white, or polished rice, and strongly urged that international action be taken among the governments of the Far East looking toward reducing the consumption of polished rice and replacing it with unpolished rice. After outlining various measures by which this might be accomplished, he was of the opinion that its quick accomplishment could most certainly be brought about by placing a tax upon the white rice, and permitting unpolished rice to be sold under terms and conditions as existed at the time the tax on white rice went into operation. In this way, on account of the small extra cost entailed upon Europeans and others who eat small quantities of white rice, no opposition would be encountered, and the masses would probably be willing to use slightly polished rice if no change was made in the price. He also stated that in order to put the question of rice polishing upon a uniform basis, a standard would have to be adopted. He suggested that the amount of phosphorous pentoxide present be used as an index of the degree to which polishing had been done. A safe rice would be one that contained 0.4 per cent. or more of phosphorous pentoxide, and an unsafe rice one that contained less. (See MEDICAL RECORD, March 16, 1912, p. 516.)

This paper precipitated considerable discussion and differences of opinion as to whether it was advisable for a medical congress to advocate a fiscal measure, even though this was done with a sanitary instead of a fiscal end in view. Some of the delegates went so far as to state that they were of the opinion that no recommendation should be made to the various governments until it was known in advance that such recommendation would be acceptable to them. The discussion finally resulted in the passage of the following resolution: "*Resolved*, That the results of the work submitted to this meeting of the Far Eastern Association of Tropical Medicine have been to confirm the accuracy of the resolution adopted at the meeting in 1910, and it is resolved to adopt as a standard that a harmless rice shall contain not less than 0.4 per cent. of phosphorus pentoxide. It is further *Resolved*: (1) That efforts of an educational nature for the suppression of beriberi should be generally adopted; (2) that in view of the varying economic conditions obtaining in the different countries concerned, uniformity of legislation appears impracticable, but any action taken should be based on the work done, and the above standard of phosphorus content is recommended for adoption; (3) it is suggested that legislation which is directed either to the taxation of polished rice or of the dealers in polished rice will be the most effective."

The following is the resolution which was adopted in 1910: "*Resolved*, That in the opinion of this Association sufficient evidence has now been produced in support of the view that beriberi is associated with the continuous consumption of white (polished) rice, as the staple article of diet, and the Association accordingly desires to bring this matter to the notice of the various Governments concerned."

The next paper was entitled "Beriberi," and read by Dr. H. Fraser of Kuala Lampor. This paper dealt with beriberi in practically the same manner as that of the preceding speaker.

The next paper was entitled "Beriberi at Saigon," by Dr. M. L. R. Montel. Dr. Montel stated that the experiences in connection wth epidemics of beriberi coincided very largely with the so-called rice origin of the disease, but that some experiences were had near Saigon which could not be entirely explained on this hypothesis. He related an instance in a monastery and a convent, where the conditions were more or less the same, and yet, in one, beriberi frequently occurred, while in the other beriberi outbreaks were never known. The monastery and convent were located in the same area of the town, and only separated by a small stream. In the monastery rice was consumed a few days after it was hulled, and no beriberi cases occurred. In the convent much the same rice was used, but large quantities were hulled at a time and stored, and in this institution beriberi outbreaks were quite common. From this fact Dr. Montel inferred that outbreaks of beriberi must in some way be connected with conditions which are caused by its being stored over a longer period of time.

The next paper was entitled "Beriberi in Japan, and was read by Professor Y. Fenchi. In this connection it may be remembered that at the meeting of the Far Eastern Medical Association which was held two years ago in Manila, the Japanese delegates who were present had disagreed entirely with the prevailing opinion at the congress that beriberi was connected with the continuous consumption of polished rice. However, the professor stated that since that time they had made extensive experiments with the white, or polished rice, and they were satisfied that it was an important factor in beriberi. He showed charts on which were recorded an interesting series of the varying proportions in the eosinophiles in oncoming beriberi, and their disappearance as the patient convalesced. He also made a series of experiments with an extract of spleens, and with this substance he was able to obtain almost the same curative properties which were reported by Chamberlain and Vedder with their rice extract.

OUR CANADIAN LETTER.

(From Our Regular Correspondent.)

SMALLPOX IN THE PROVINCE OF QUEBEC—ASSOCIATION OF MEDICAL OFFICERS OF CANADIAN MILITIA—MEETING OF ONTARIO MEDICAL ASSOCIATION IN TORONTO—DEATHS FROM TUBERCULOSIS IN ONTARIO—MEDICAL RECIPROCITY IN CANADA—NOVA SCOTIAN HOSPITAL FOR THE INSANE—MEETING OF CANADIAN HOSPITAL ASSOCIATION—SANATORIA FOR TUBERCULOSIS IN NEWFOUNDLAND—REGULATIONS GOVERNING THE PRACTICE OF MEDICINE IN ALBERTA—OPEN FELLOWSHIP AT McGILL UNIVERSITY—DEATH RATE OF MONTREAL IN 1911.

MONTREAL, March 19, 1912.

FROM public health and medical standpoints the most important problem in Canada is how to deal with the smallpox situation in the Province of Quebec. The disease has been simmering with an occasional explosion in the province for a considerable time. There are no signs that the epidemic, which is now recognized as widespread, is abating. During the month of February the disease has been reported from eighty-one municipalities. Dr. Beaudry, the Chief Inspector of the Provincial Board of Health, has estimated recently that there are more than 75,000 cases in the province, besides many cases which are kept secret. The contagion is distributed all over the province, but is especially rife in the north from Ottawa to the Lake St. John district, as much of it originates in the lumber camps. Since the beginning of the epidemic the Provincial authorities have found smallpox not reported to the proper authorities. No fewer than five convents and two colleges have been found guilty of not fulfilling this obvious duty to the public. In fact, the situation is very complicated and extremely difficult. Dr. Elzear Pelletier, who uses the iron hand in the velvet glove with great discretion in conjunction with his able coadjutor, Dr. Beaudry, has been employing his utmost endeavors to check and stamp out the epidemic by advice and recommendations, but has discovered that more vigorous measures must be put into force before a successful issue can be reached. Last spring the Provincial Board of Health issued an order requiring municipalities to pass and carry out a vaccination by law. The order in so far as it was executed, did a great deal of good but, unfortunately, antivaccinationists created an agitation and to some extent paralyzed these efforts. In only one municipality, however, was it necessary to obtain a judgment to cause its members to pass the required law. Thus, so far as the passing of the law has been concerned, success has attended the efforts of the board. One of the main arguments which the authorities have had to meet has been the English "conscientious" objection clause. As Dr. Pelletier wisely remarked, how can a man ignorant of medicine have a conscientious objection to vaccination? A better name for it would be an "ignorant objection." The truth seems to be that the disease being in a mild form, it is lightly regarded in Quebec. Further, the leading people of the province do not seem to appreciate the gravity of the situation. The public disregard is said to be extraordinary. A school-mistress in one place was found teaching in school scarcely recovered from the complaint. Persons suffering from the malady go to stores and postoffices and mix with their fellows as if they were in ordinary health. Familiarity has bred contempt and it is even hinted that to be picoté is looked upon in the Province of Quebec as to some extent a mark of distinction. Nevertheless, although the great majority of the cases have been of the varioloid type, a few cases of the hemorrhagic form have been reported. Several medical writers have pointed out this is of sinister augury, as before the awful epidemic of smallpox which swept the Province of Quebec some twenty years ago, the cases had been of a mild type. During that epidemic no less than 6,000 fatalities from the disease occurred in one year in the city of Montreal alone. Dr. Elzear Pelletier and his colleagues have fought and are fighting hard to overcome prejudice and ignorance, and it is to be hoped in the interests of the community at large that they will gain the victory.

The annual meeting of the Association of Medical Officers of the Canadian Militia was held in Ottawa under the presidency of Major Le Bel, A. M. C., Quebec, on February 28 and 29. The attendance was the largest since the formation of the society. A number of most interesting and important papers were read. Sir James Grant's paper on the condition of the hospitals in the Northern Army in 1861 and again in 1864, he having been sent by the Government of Canada to report upon them, was an interesting and valuable piece of medico-literary history. Colonel Jones, Director General, in his paper showed how much work would necessarily be thrown on the regimental service in battle, under modern tactics, taking into consideration modern arms and modern surgery. Dental Surgeon Lantier, A. M. C., brought out in his paper many important points regarding the dental sanitation of an army. An excellent paper was presented by Staff Surgeon Digby Bell of the Canadian Navy, on Physical Training. The greatest interest of the meeting centered in the discussion on the "Clearing Hospital"; its organization, equipment and functions, as well as its tactical use, were carefully gone into by the various speakers.

On Wednesday evening the members dined at the Russell House, where a very pleasant time was spent, speeches being made by the Minister of Militia Colonel Hughes, Surgeon-General Sir F. W. Borden, K. C. M. G., Colonel Jones, D. G. M. C., and Lieut-Colonel Shillington. On Thursday evening Major Le Bel, the retiring president, enter-

tained the members and a large number of guests at a smoking concert. The following officers were elected for the ensuing year: *President*, Lieut-Colonel A. T. Shillington, A. M. C., Ottawa. *Secretary*, Captain T. H. Leggett, A. M. C., Ottawa. *Treasurer*, Captain McKelvey Bell, A. M. C., Ottawa. The next meeting will be held in Ottawa in February, 1913.

Dr. W. J. Dobbie in his annual report of the Toronto Free Hospital for Consumptives shows that there has been a notable decrease in the death rate from this cause during the past decade. In the ten years up to 1899 the death rate from tuberculosis in Ontario was increasing. In that year the figures amounted to 3,405, or 11.8 per cent. of the total deaths. In 1908 the deaths from tuberculosis were 2,511, or 7.6 per cent. of the total deaths. Up to the year 1899 there were no institutions for the treatment or care of tuberculosis in the province. There were no dispensaries. Now there are twelve sanatoriums and hospitals and others projected, four dispensaries, and so on. Dr. Dobbie argues with seeming justification that the decline from 11.8 per cent. to 0.8, the percentage of deaths from tuberculosis to total deaths given in the 1910 report, is due at least in some measure to the efforts already put forth to stamp out the disease. Eighty-three cases of tuberculosis were reported in Toronto in February as against 45 for the previous month. Dr. Hastings, the Medical Officer of Health for the city, attributes this increase to a large extent to the fact that such cases are better reported. It is stated that the local Boards of Health in Ontario are to give place to experienced medical officers. In order to carry out this scheme, the province will be divided into several districts.

Medical reciprocity between the different provinces of Canada was approved recently by the Legislature of the Legislative Assembly of the Province of Quebec. The Nova Scotian Hospital for the Insane is erecting a new building. It will accommodate about seventy patients. The Canadian Hospital Association will hold its next meeting in the Parliament Building, Toronto, on April 4, 5, and 6. Messrs. Reid Bros. and the Reid Newfoundland Co. have made the offer to erect and equip sixteen tuberculosis sanatoria as a gift to the Government of Newfoundland. The Government, by Premier E. P. Morris, has accepted the offer. There is to be one large central sanatorium at St. John's with a smaller institution in each of the sixteen electoral districts.

The Medical Council of Alberta has been enjoined to admit upon the register the name of any person who can produce a certificate from the registrar of the University of Alberta that he is qualified to practise osteopathy or homeopathy and the examination of candidates is to be undertaken by the university. It is expressly provided that the approval of the College of Physicians and Surgeons shall not apply to the subjects in which osteopaths and homeopaths shall be examined. Section nine provides that any person who has practised osteopathy in Alberta for at least four months previous to the passing of the act shall be granted a certificate without examination. The person, however, must have the approval of the American Osteopathic Association.

Applications were invited by the Medical Faculty of McGill University for the Douglas Medical Research Fellowship of the value of $1,000, tenable for one year with possibility of reelection for the second year. The holder of the fellowship will be required to undertake such investigations as shall demand a combination of study in hospital wards with research in the pathological department of the university. Candidates, who must be graduates of a recognized medical school, are requested to indicate the line of work they propose to undertake and to afford evidence of original research already accomplished.

Montreal had 9,974 deaths in 1911, 5,110 males and 4,864 females, giving a death rate of 21.30 per 1,000. The deaths of children under five years of age numbered 5,355, being 53.69 per cent. of the general mortality.

The Disappearance of Ovarian Tumor After Vesicular Mole. S. Rushmore.

Outdoor Treatment of Puerperal Infection.—E. B. Young and J. T. Williams state that the outdoor treatment has reduced the mortality of severe puerperal infections by nearly 20 per cent. (2) This treatment probably exerts its action chiefly by increasing the amount of hemoglobin in the blood. (3) Sunlight is probably quite as important as fresh air. (4) Curettage is contraindicated in puerperal infection, because it increases the mortality nearly 10 per cent. (5) A single intrauterine douche of sterile salt solution should be the only local treatment, and some writers deny the value of even this. (6) Antistreptococcic serum and vaccines have not proved of much value. (7) The outdoor treatment is the most effective known at present for puerperal infections, but the search for new methods should be continued.

Tuberculous Epididymitis.—J. D. Barney, from an analysis of the end results of seventy-one cases of tuberculosis of the epididymis draws the following conclusions: 1. After the removal of one or both epididymes the large majority of patients are found to be in good condition and to have gained weight. 2. In two-thirds of the cases there is no demonstrable evidence of tuberculosis elsewhere than in the genitourinary tract. When present it is most commonly found in the lungs or bones, but any organ may be attacked. 3. Renal tuberculosis rarely follows an infection of the epididymis. 4. Tubercle bacilli were present in eight out of ten urines as shown by the guinea-pig test. These urines also contained blood and pus, while those giving a negative reaction were normal. 5. A small majority of cases have a normal urine, and no urinary disturbances either before or after operation. 6. Postoperative sinuses are found in 25 per cent. of cases, but as about two-thirds of the patients were seen during the first year after operation, and as many sinuses remain open for several months, this figure would be ultimately much reduced. The use of tuberculin after operation hastens convalescence and the closure of sinuses more than any other measure. 7. No case on whom epididymectomy was performed is known to have had a recurrence in the corresponding testicle. 8. Tuberculosis of prostate and vesicles is found in more than half of the cases. 9. In a very large majority the sexual function is undisturbed, but the semen is found to be sterile in 85 per cent. 10. A comparison of many orchidectomies with a few epididymectomies shows the latter to have resulted more favorably. It is a fact, however, that infection of the second epididymis is to be expected, with or without opera-

tion on the first epididymis, and whether that operation be epididymectomy or orchidectomy. II. The mortality of operations, for tuberculosis of the epididymis is 5.47 per cent., the cause of death being a general miliary tuberculosis.

Bone Lesions Accompanying Chronic Leg Ulcers.—W. P. Coues states that: 1. Long-continued ulceration of the leg, whether varicose, specific, or undetermined, is often accompanied by extensive changes in the underlying long bones, often only demonstrable by radiographs. These changes may be specific or non-specific. A careful examination and thoughtful interpretation of the radiographs will differentiate the specific from the non-specific bone lesions. 2. These underlying lesions of bone are of great importance as regards treatment, as they occur too commonly to be ignored or passed over as occasional. 3. Do the ulcers of the soft parts cause the bone condition or do the bone lesions cause the ulceration of the soft parts? The author believes that in the long-continued ulceration this finally has its effect on the periosteum. In the specific cases the bone process is not by direct extension in the majority of cases, but the bone lesions are an index of the probable character of the ulceration of the soft parts. Some cases, however, undoubtedly arise from direct extension of a specific process in the periosteum, extending outward to the soft tissues and forming an ulcer. 4. Iodide of potassium helps both kinds of cases, specific or non-specific, many of these cases having a high blood pressure. 5. All cases of leg ulcers should have radiographs taken of the underlying bones, and be carefully tested for tabes. Many of them, which are supposed to be varicose on account of accompanying varicose veins, are really specific.

Colds.—A. Jacobi quotes the fanciful notions of ancient and modern writers with respect to the supposed relationship between cold air and water and various pathological conditions. The mechanism of "catching cold" depends upon disturbances of the surface circulation, which cause internal congestions. Bacterial infection is not a prerequisite in this process. The prevention of colds requires the maintenance of general health, and exercising by means of cold sponging or cold baths the reactive power of the skin.

The Cause of Myopia.—By W. H. Bates. (See MEDICAL RECORD, February 7, 1912, page 338.)

The Circulation of the Cerebrospinal Fluid.—S. P. Kramer has studied this subject by means of injecting methylene blue into various parts of the cerebrospinal axis in dogs, then killing the animals shortly afterwards, and noting the distribution of the dye. When the methylene blue was injected into the lumbar portion of the subarachnoid space it was noted that the outer surface of the spinal cord was stained for a varying distance up; at times all the way to the medulla oblongata, at other times not so far. The floor of the fourth ventricle, however, was stained, as were the cerebellum, the aqueduct, the entire ventricular system of the brain, the subarachnoid space at the base, as well as the sheaths of the cranial nerves. This is due to the fact that the central canal of the cord is lined with ciliated epithelium, and ciliated epithelium in canals wash toward the orifices of outlet, and these are for the cerebrospinal fluid, the lymph spaces in the sheaths of the cranial nerves at the top of the neural tube. This finding is suggestive as a possible explanation of the pathogenesis of poliomyelitic disease. It shows how it is possible for a poison to reach the meningeal surface of the cord and the central gray matter, and leave the rest of the cord unaffected. Acute poliomyelitis is a disease of childhood and is also an ascending paralysis. An ascending poliomyelitis also occurs in adults, though more rarely than in children. It is possible that this is due to the fact that in but a fraction of adults the central canal exists as an open tube.

Home Operations.—W. F. Burrows states that in view of the ease with which the home may be prepared for operative work; the slight trouble entailed upon the family, and the comfort of having the patient, especially during convalescence, near them; the attainment of the Trendelenburg position upon any table by means of a suitable device; the lack of danger in most instances of proper surgical procedures; the modified postoperative treatment, whereby discomfort is at a minimum; the probability of a rapid recovery; and the risk that many cases run in transportation; the majority of operative procedures, other things being equal, should be performed at the home. The room selected is but for a short time transformed and, with pleasing surroundings, recovery is hastened and the outcome is more to be commended on account of the close relationship held throughout by the general practitioner, who not only directly follows his case, increasing his diagnostic ability, but also retains the confidence and highest esteem of his patient.

Contracted Pelvis and Induction of Labor.—E. MacDonald states that the induction of labor is the suitable treatment in contracted pelves of moderate degree, provided the size of the baby is estimated by measurements of the uterine fundus and fetal head and by the relation of the fetal head to the pelvis. Labor may then be induced at the most suitable moment, so as to get the largest sized baby that will pass the pelvic strait and avoid unnecessary prematurity. It is essential that mothers be examined at least four weeks before the expected labor in order to estimate the proper time for induction. The lowest limit of pelvic contraction, suitable for treatment by induction of labor, is 8 centimeters true conjugate, as this will permit the birth of a 2,500 gram (five and three-quarter pounds) baby, with an average 8 centimeter biparrietal diameter. This weight of baby avoids the dangers of unnecessary prematurity and has a mortality but little more than the average. Better results are obtained with pelves larger than this, but this is the lowest limit. If the child is measured in all cases the dangers of prolonged pregnancy and overweight babies will be avoided, because they will be recognized and treated. Cesarean section has a mortality in 3000 cases of 7 per cent. and should be reserved for cases with pelvic contraction through which it is not advisable to have a baby pass (below 8 centimeters), or for cases in which the child has already grown too large to pass through the moderately contracted pelvis. In these cases it may be done as a primary operation.

Bacteriology of Trachoma.—A. W. Williams reports the work that has been accomplished at the Research Laboratory of the New York City Department of Health in the study of the bacteriology of trachoma. From cases of this disease there were isolated gonococcus-like colonies of a small bacillus, which was Gram negative and strictly hemoglobinophilic, with a morphology and staining characteristic very similar to those of some of the trachoma inclusions. It is concluded that bacillus and inclusion are probably identical in papillary trachoma, and that the bacillus is probably the cause of the disease. The hypothesis that one or more of the group of hemoglobinophilic bacilli is the cause of trachoma explains many other hitherto unex-

plainable phenomena of this disease, its irregular onset; its insidious course; its variable contagiousness with its exacerbations of secretion, and the continued presence of trachoma in certain districts where helping causes are present.

Transduodenal Lavage.—M. E. Jutte recommends in various conditions the use of this procedure which may be carried out by means of introducing a duodenal tube and using various fluids for irrigating purposes. It is suggested that the cause of some of the obscure chronic ailments may be traced to the intestine, that the removal by transduodenal irrigation of the toxins produced in the course of fermentation and putrefaction will aid digestion and assimilation and will bring about improvement or recovery in such diseases as bronchial asthma, primary and secondary anemia, gout, rheumatism, arthritis deformans, toxic albuminuria, so-called biliousness, chronic constipation, and other intestinal disorders.

X-ray Diagnosis of Pregnancy.—P. S. O'Donnell states that he has developed a technique in the use of the *x*-rays which not only shows clearly the fetus in the uterus, but also is capable of showing many abnormalities. The position of the fetus can be clearly determined after the fourth month. The exposure is less than one-fifth of a second with a medium tube. In the diagnosis of pregnancy the *x*-ray has a limited field, as the usual methods are generally sufficient, but in fat women or when there is need of differentiation between pregnancy and a large fibroid, it may be helpful.

Malt Soup in Nutritional Disturbances of Infants.—J. M. Brady states that malt soup is prepared as follows: Two ounces of wheat flour are mixed with 11 ounces of whole milk and then passed through a sieve. In a second vessel 3 ounces of extract of malt are mixed with 20 ounces of warm water. The two mixtures are then poured into a porcelain vessel, 2½ drams of 11 per cent. carbonate of potassium are added, and the whole is cooked with constant stirring for twenty minutes and then brought to a momentary boil; any loss through heat is made up by the addition of boiled water. This mixture has a formula of fat 1.20, protein 2.00, carbohydrates 12.00, and has a caloric value of 800 to the liter. The above is designed for infants with a body weight of from 6½ to 10 pounds from the third to the ninth month. For infants under 3 months of age the flour is reduced to 1 ounce and the malt-extract to 2 ounces. According to Keller and Czerny, there is a definite indication for the employment of this food, *i.e.* in the milk nutritional disorder described by them. It begins insidiously with irregular gain or loss in weight, and increase of food does not mend matters. The baby becomes pale and the skin loses its elasticity. The muscles are flabby. Restlessness, peevishness, and inability to sleep are common. Abdominal distention is often present, and sometimes vomiting. The stools are grey or whitish and very dry, frequently foul smelling. Their reaction is markedly alkaline. They may become loose and acid in case of complicating dyspepsia or intestinal infection. Lacking proper treatment many of these cases develop marasmus. The disease is a severe metabolic condition and non-bacterial. It is caused by a high percentage of fat in the food, and owing to the recent popularity of top mixtures it has become frequent. The therapeutic test, diminution of the fat percentage, reveals the condition. The author has used malt soup in this condition with advantage and states that even if marasmus has appeared the treatment is sometimes successful. It is not adapted to infants under 3 months of age in whom albumin milk is more apt to be of service. In diarrheas it is frequently of inestimable value.

A New Test-Meal.—By D. Roberts. (See MEDICAL RECORD, Vol. 70, page 1025.)

Frequency of Surgical Lesions of Kidney and Ureter.—E. M. Stanton notes that surgical lesions of the kidney or ureter of at least practical diagnostic interest are found in approximately from 4 to 6 per cent. of patients coming to autopsy and that the great majority of these could have been at some time cured or greatly helped by timely, accurate diagnosis and surgical treatment. With very few exceptions in these cases the renal lesions were the chief cause of death, and they constitute a group that are particularly fatal, sometimes killing quickly but more often adding to the handicap which determines the fatal outcome whenever the bodily resistance is diminished by intercurrent disease. In the table showing the frequency as shown clinically in hospital practice, compiled from statistics from ten representative American hospitals during the years 1908 to 1910 inclusive, about 1 per cent. of the patients suffered from surgical kidney disorders, which the author thinks probably represents a fair average of these conditions as recognized by the average standards of diagnosis. In 25,243 surgical cases treated in three American hospitals where cystoscopic and *x*-ray examinations are made in all suspicious cases there are 527 operations on the kidney and ureter, or nearly 2 per cent. of the whole, as compared with about 1 per cent. in seven hospitals in which the *x*-ray and cystoscope are used to only a limited extent.

Normal Urine.—J. H. Long emphasizes the practical difficulty in giving a concise answer to the question, what is normal urine. Normal urine is not only a function of the diet, and this is quantitatively the main factor, but it is a function also of certain idiosyncrasies in each individual. It is this factor which makes the greatest difficulty in coming to a conclusion in many a doubtful case, and which suggests the necessity of admitting a much wider range in certain factors than is usually the case. Our more modern quantitative methods for the urine should permit a closer relation between clinical observations and chemical findings in those cases in which the question of normal limits may assume considerable practical importance.

Epidemic Sore Throat.—D. J. Davis and E. C. Rosenow report an epidemic of severe sore throat that has prevailed in Chicago for the past three months. The infection was characterized by a sudden onset with severe prostration, by glandular enlargement, and frequently by serious complications. The organism isolated was an encapsulated hemolytic streptococcus of high virulence. It appeared to occupy a position between the ordinary hemolytic streptococcus and the *Streptococcus mucosus*. It was not a pneumococcus. The increase of the capsular substance on animal passage and its loss on artificial media suggested that the capsule and high virulence were the result of frequent human passage and might serve to explain the unusual tendency to complications and the general severity of the disease.

Clinical Use of Carbon Dioxide with Oxygen.—E. Levi states that it has been shown that carbon dioxide

is one of the most important of the body hormones, exercising a regulative influence on the action of the heart, on the tonus of the blood-vessels, and especially on the respiration. This has been largely due to the Italian school of physiologists, but the author specially mentions the investigations of Yandell Henderson on acapnia as a factor in shock. From these he was himself led to consider the practicability of utilizing mixtures of carbon dioxide with oxygen for the purpose of stimulating the bulbar centers in those cases in surgical practice in which they are temporarily paralyzed by the anesthetic or trauma. His experiments, first tried on animals, have shown that this mixture of gases, when properly diluted, is a therapeutic agency of extraordinary potency. His experiments were first tried on animals and his success with these led him to employ it on human beings. The method has been employed, with at times brilliant success, particularly in cases in which the breathing had become shallow, irregular, or of the Cheyne-Stokes type. For nearly two years the method has been employed by Professor Burci, the head of the surgical clinic in Florence, who has such faith in the method that he has made a standing order to have the carbon dioxide oxygen mixture always at hand for immediate use in case of need. The best results are obtained with a mixture containing 15 per cent. of carbon dioxide, and it is not their custom to wait until complete respiratory paralysis or profound shock has been produced, but to give inhalations of the mixture on the appearance of the slightest tendency to failure of respiration or cardiac function. Even in profound shock the results are beneficial, and in no case have they observed any ill effects from the treatment. The method has been found serviceable in cases of profound toxemic asthenia as a substitute for the peripheral stimulation ordinarily used. The observations of the Florentine surgical clinic seem to explain to some extent the good effects of artificially reduced circulation in narcosis. It seems probable that the remarkable rapidity of recovery in such cases is due to the sudden return to the general circulation of a large amount of blood rich in carbon dioxide when the lower limbs are unbandaged. Following up this suggestion they found that the use of a mixture containing 10 to 15 per cent. of carbon dioxide was very effective in awakening the patient after anesthesia. It also decreases the tendency to postanesthetic vomiting.

Atropine Therapy in Diabetes.—H. O. Mosenthal reports two cases of diabetes in which he tested the atropine treatment advised by Rudisch and by Forchheimer. The drug was used in doses of from 1/100 to 1/25 of a grain daily, until toxic effects were observed. The glucose was determined by Benedict's method, the ammonia by that of Folin and the nitrogen by the Kjeldahl process. The results give no indication that atropine sulphate causes any change in the carbohydrate tolerance of sufficient importance to make it of clinical value in the treatment of diabetes.

Glycosuria.—A. E. Garrod, in concluding his series of articles on this subject describes the forms of glycosuria associated with disturbances of the thyroid gland, the pituitary body, and the adrenals. An excess of thyroid or of pituitary secretion tends to induce glycosuria. The author emphasizes the fact that many morbid different conditions bring about disturbances of the metabolism of carbohydrates and that such disturbances manifest themselves in several different ways: now by a lowering of glucose tolerance without actual excretion of sugar in the urine; now by a spontaneous excretion of sugar in smaller or larger amount during limited periods of days, weeks, or months; and now by a persistent glycosuria, accompanied in its higher grades by the associated symptoms which go to make up the clinical picture of diabetes. Moreover, disturbances of these several grades may be induced in different cases by one and the same cause, or in the same case at different times. The effect of this is to obliterate in one's mind the conception of diabetes as a sharply defined disease, and to present the malady as merely the maximal phase of a series, rising by gradual steps from the normal of metabolism, just as myxedema is the culminating point of the almost insensible grades of hypothyroidism. Between the sufferer from grave diabetes and the potential glycosuric there is a striking contrast, but the gulf which separates them is bridged over by intermediate cases of all degrees of severirty. While it is true that in some cases of diabetes the nervous system is evidently at fault, and that in others the thyroid, the pituitary, or the pancreas is the seat of disease, in the great majority of cases which are encountered in practice one can find no indications of the underlying lesion upon which the metabolic derangement depends. The various tests of pancreatic efficiency give uncertain or negative replies; no ductless gland is evidently the seat of disease; no intestinal disturbances point to an origin in the alimentary tract, and no cardiovascular changes help one to classify the case. There is, to all appearance, a sheer, wanton, metabolic insanity. Nevertheless, one can hardly doubt that in such cases there is an underlying morbid cause at work.

Malignant Disease of the Testicle.—Sir Henry Morris reports the histories of two cases which show that columnar carcinoma of the testicle may remain quiescent, or the patient may be absolutely free of recurrence for many years; but the expectation is always that the disease will ultimately recur, though it may be only after a long time. When, therefore, this fact is taken into account, together with two others—namely, (1) that it is impossible to detect the early secondary infection of the iliolumbar lymph-glands; and (2) that the extirpation of these glands, when obviously enlarged subsequent to removal of the testis, is an operation of magnitude and severity, and has been very discouraging hitherto in its results—when these facts are taken into consideration, one may well be led to hope that the practice of the "radical" or "improved" method of excision of the testis may prove to be successful. So far, however, in the 17 cases reported of this "improved" operation, there is little, if any, foundation for such hope. In some of the operations the affected glands could not be removed, or, in other words, the "improved" method was found to be impracticable; in other cases in which the glands were successfully removed at the time, the disease soon returned; while in the rest insufficient time has elapsed since the operation to permit of any conclusion being drawn as to the ultimate result. Still, hope need not necessarily perish because as yet little, if any, encouragement can be derived from the very limited existing experience. Meanwhile the low malignancy of carcinoma testis, and the long histories of such cases as the author has recorded will often afford a prospect to any given patient of prolonged or entire immunity after the testis and cord have been excised by the old method.

Toxic Symptoms Following Administration of Salvarsan.—J. McIntosh, P. Fildes and H. Dearden conclude that the phenomena of rigors in syphilis treated by salvarsan dissolved in toxic saline solution and rigors occurring in secondary syphilis after the use of non-toxic saline solution are due to two entirely different factors. In the first case they are due to the dead bacteria in the water acting as a foreign protcid, while in the second they are due to bodies liberated from the spirochetes after their destruction. The elimination of the more excessive toxic symptoms by the use of bacterium-free saline solution is a matter of some value; so much so that Ehrlich urges that everyone who makes use of these injections should distil his own water. Commercial distilled water is often grossly contaminated with bacteria, and the difficulties in the preparation of a pure saline solution are considerable. It is suggested that in the absence of toxic symptoms due to the water the slight toxicity due to the salvarsan as such will be more easily borne, and larger doses may therefore be used. For the last six months the authors have never given an adult less than the maximum (0.6 gram) at one time.

"Aching Throat."—W. H. Kelson states that this condition is not synonymous with sore throat. In the former there may be no evidence of disease in the pharynx. The patients who come complaining of this trouble have generally arrived at, or are approaching, middle life, and the aching may vary very considerably in degree and somewhat in character. On examination they may be found to have the signs of chronic pharyngitis, with swelling, congestion, and catarrh; hypertrophy of the pharyngeal bands and granular patches, associated with coughing, hawking, and other efforts, varied and anomalous, some voluntary, others reflex, to clear the throat. Also there may be associated with it enlargement of the postnasal, faucial, and lingual tonsils; the first least, the last most commonly, or nasal obstruction and discharge, also enlarged veins, bad teeth, and enlarged glands. Experience has shown that aching throat is more commonly associated with flatulent dyspepsia than anything else, and this seems to act either by the formation of toxins; or possibly the aching may be a referred pain, such as that which occurs in the ear so commonly in disease of the larynx and upper part of the esophagus. There may also, however, be local conditions which, if they do not actually cause, certainly accentuate, aching throat; these must be sought out and dealt with in obstinate cases, not forgetting, Kelson says, that the condition of the nose and accessory sinuses has a very direct and positive bearing on the state of the pharynx, as also have the teeth.

Treatment of Inoculated Rat Sarcoma.—H. G. Grünbaum and A. S. Grünbaum state that in a previous communication they published the results of some experiments on the treatment of malignant disease in rats and mice, showing that by the injection of antivenom (horse) serum it was possible to effect regression of inoculated tumors in rats provided they did not exceed 1.5 centimeters in diameter. The authors have found since that by the simultaneous administration of adrenalin with the antivenom serum (Pasteur Institute) yet larger growths can be made to disappear in these animals.

Vaccine Treatment of Pneumonia.—N. Raw reports the results he has obtained with the use of stock vaccines of pneumococci in the treatment of 207 cases of pneumonia. The mortality was a little over 16 per cent. The vaccines did not seem to have any appreciable effect in hastening the crisis. The effect, however, on the pulse is always good, and there is a very decided diminution of delirium. There is also a notable absence of complications in cases so treated. The author is convinced that pneumococcus vaccine is a valuable aid in the treatment of pneumonia.

Auricular Fibrillation.—J. G. Emanuel states that there are practically no symptoms that are peculiar to continuous irregularity of the pulse—that is, to auricular fibrillation—apart, of course, from the symptoms due to the accompanying valvular disease or dilatation that may be present. In other words, a patient with a continuously irregular pulse may be no more conscious of the irregularity than is another patient of the regularity of his pulse. There may be no symptoms at all, and the patient may be able to perform arduous labor, physical or mental, for many years though the heart remain permanently irregular. The irregularity, however, hampers the heart's action, and, though the favorable condition may persist for years, symptoms of heart failure arise sooner or later, insidiously or rapidly, the symptoms being dyspnea on exertion, edema, cyanosis, etc. The cases fall into two groups: (1) A rheumatic group. The patients are young; the average of 45 cases with a history of rheumatism was 34. (2) A non-rheumatic group. The patients are past middle age; the average of 22 cases was 58. In the rheumatic group valvular disease may or may not be present, but if present, mitral stenosis is by far the most common form. The non-rheumatic group includes that form of heart disease generally known as myocardial degeneration, cardiosclerosis, or the senile heart. It may be associated with arteriosclerosis, granular kidney, aneurysm, etc.

The Management of Cardiac Failure in Diphtheria.—E. F. Coghlan states that the treatment of cardiac failure accompanied by persistent vomiting and occurring in the course of or after diphtheria should be conducted on the following lines: The head should be low to prevent cerebral anemia, while the foot of the bed should be elevated. Patients during the stage of cardiac depression become restless and throw off the bedclothes. They should therefore be warmly clad, and for the same reason hot-water bottles should be placed in the bed. All food by the mouth should be stopped and nutrient enemata administered. The rectum should be irrigated twice daily with warm boracic acid solution, otherwise irritation may be set up, and retention of nutrients become impossible. Cardiac depression must be combated by the administration of medicines. Various drugs have been used for this purpose, chief among them being strychnine, belladonna, and adrenalin. Since administering them in combination hypodermically the author has had four successful cases, though, of course, he has also had failures. The formula used is as follows: Atropine sulphate, 1/100 grain; strychnine hydrochloride, 1/100 grain; adrenalin chloride solution (1 in 1,000), 5 minims; water, 5 minims. This is to be administered hypodermically every four hours. Thirst is first met by the administration twice daily of small enemata of normal saline solution, while teaspoonful doses of iced water may be allowed as soon as the vomiting ceases. Dryness of the mouth may be alleviated by the application of such remedies as glycerine and boracic acid, half strength. Pain is most rapidly relieved by the frequent application of hot fomentations to the precordium. Constipation is to be combated by small enemata of glycerine and water.

Adrenalin in Cardiac Dyspnea and Dropsy.—J. C. Voigt has had under his care several cardiac cases in which dyspnea and dropsy were prominent symptoms, and in which suprarenal gland was administered. More or less severe dyspnea was relieved, sometimes by the hypodermic injection of from 5 to 15 minims of the 1 in 1,000 adrenalin solution, at other times by a 5-grain tablet of the suprarenal gland substance administered by the mouth. When the dyspnea was not very severe, the dose of adrenalin solution injected hypodermically was from 5 to 10 minims and the 5-grain tablet of the gland substance was halved for each dose by the mouth.

Wassermann Reaction on Post-Morten Serums and Cerebrospinal Fluids.—J. P. Candler and S. A. Mann conclude that while their observations lead them to consider that the reactions on the blood and cerebrospinal fluid removed from the cadaver before decomposition has commenced will give reliable results, they agree with Luksch that decomposition is liable to alter the reaction, as may also a terminal microbial infection. This change, however, is not confined to the alteration of a negative to a positive result, but may alter a positive into a negative: and the authors point out that decomposition may similarly influence the result of the test on fluids and serums removed during life. To ensure satisfactory results on post-mortem material it is, therefore, necessary to remove the cerebrospinal fluid and blood as soon as possible after death. The serum should be separated and inactivated at once, and the cerebrospinal fluid should be carbolized, unless the test can be applied the same day.

Statistics of Blindness.—W. C. Rockliffe presents an analysis of 590 cases of blindness that have come under his observation during the past 28 years at the Hull Blind Institution. He believes that ophthalmia neonatorum is generally considered to be the primary cause of blindness. Doubtless in years gone by this was so, but from the author's figures it is clear that to-day atrophy of the optic nerve ranks first, and that much has yet to be discovered in the preventive and therapeutic treatment of these cases. Further, atrophy occurs in the middle decades of life, especially between the ages of 40 and 50, and another point of interest is that death usually follows spinal atrophy in four or five years, while those with cerebral atrophy live to a much longer period.

Altruistic Diseases.—Von Hansemann revives this expression in connection with diseases due to affections of the hormone secreting organs such as diabetes, myxedema, Basedow's disease, acromegaly, Addison's disease, parathyroid tetany, etc. These are only highly concrete examples due to serious lesions of the organs in question. In a larger sense habitual secretory anomalies of the latter stand in causal relation to the so-called dyscrasias. It is probable that all organs have internal secretions for with the exception of the spleen, each one is indispensable to life. The isolation of the spleen in this respect is doubtless due to the fact that it does not constitute a complete system in itself, but is merely a part of a system. The position of the pancreas is somewhat anomalous, for it has a highly elaborate external secretion together with an important but somewhat problematic internal secretion. In lesions of this organ only one secretion may be compromised or both may be simultaneously affected. The view that the pancreas is a complex structure, a gland within a gland, will probably be found erroneous; for it is to be doubted that the Langerhan's islets possess the function at present attributed to them. As yet an affection characterized by increased hormone production by the pancreas exists in theory only. Since other structures having internal secretions all give rise to syndromes due to hyperfunctioning, we assume that an analogous affection should proceed from the pancreas. If there is diminished hormone production, inability to oxidize carbohydrates results. In the opposite state there should be increased carbohydrate tolerance, but we do not know in what clinical form this would be manifested. The genital glands are not known to give rise to altruistic diseases in the strict sense of the term, but when they are removed or destroyed the so-called secondary sexual characters suffer changes. Those which serve to characterize the former sex suffer atrophy, while those characteristic of the opposite sex may become evident. At the climacteric in the female there is also a notable predisposition to certain affections, but these are in no sense specific. The physiology of the future will doubtless pay attention to certain functions of the lungs, liver, kidneys, etc., from the viewpoint of possible internal secretions concerning which we at present know but little. The changes caused by great destruction of the lung parenchyma, for example, are exactly those which would be due purely to defective oxygenation. The author goes so far as to claim that the oxygen which reaches the blood from the lungs represents the internal secretion of the latter, while the expelled CO_2 is the external secretion.

Septic Endocarditis.—Jochmann has analyzed twenty-eight cases of this affection, as a result of which labor he is able to corroborate fully Lenhartz's conclusions based on thirty-seven cases. The affection is that once known as ulcerous or malignant endocarditis, and since the pathogenic germ is practically always present in the circulating blood, the term septic has succeeded the older adjectives. The most frequent cause is the streptococcus, and next in order of frequency come respectively the staphylococcus, pneumococcus and gonococcus. Isolated cases have been traced to other infectious organisms. There is an acute and a chronic type, and the latter has almost always been found due to a streptococcus and chiefly to one particular variety, the S. *viridans*. The acute form occurs more frequently than the chronic, and leads to death in a few days. The clinical expression is that of a profound septic infection. Individual cases vary largely with the kind of pathogenic germ and of the parent lesion. Staphylococcus cases follow felons and boils, a urinary infection, an angina, etc. Pneumococcus cases complicate croupous pneumonia. Gonococcus cases usually proceed from a gonarthritis. Streptococcus cases are preceded by streptococcic angina, otitis, infected wounds, erysipelas, etc. Endocarditis develops in about 20 per cent. of all sepsis and a marked almost constant, predisposition is furnished by old valvular heart disease, whether from acute rheumatism in youth or arteriosclerosis in later years. Naturally there may be complications due to coincident implication of other organs from the primary focus, as well as others resulting directly from the endocarditis itself, to say nothing of a generalized septicopyemia.

Action of Organ Extracts and the Hormone Theory.—Popielski has shown that all organ extracts, whether made with water, alkalies, or acids, cause complicated syndromes which may comprise nervous excitation, convulsions, vomiting, spontaneous expulsion of feces and urine, salivation, lacrymation and other examples of hypersecretion, lowered blood pressure, diminished coagulability of blood, etc. This appears to show that extracts from all organs have in common a vasodilating principle, which is not cholin. The author terms it provisionally vasodilation. The same substance is formed in proteolytic digestion and occurs in peptones. It is overantagonized by adrenalin in

its action on the blood pressure. Like secretion, vasodilation stimulates the pancreatic secretion, but in the former this activity is specific. Because of the universal presence of vasodilation in the tissues the author inclines to the belief that the hormone theory is untenable. The same idea may be seen in connection with the so-called peristaltic hormone of Zuelaer. This is present in a variety of tissues, perhaps in all of them. Its peristaltic action is due to its property of lowering the blood pressure. Therefore the peristaltic hormone and vasodilation must represent a single principle, the former containing some of the latter. Organ extracts also contain a principle having the property of raising the blood pressure, which the author terms hypertension. This he regards as being identical with pituitrin, but not with adrenalin. Therefore in place of a large and indeterminate number of specific principles known as hormones we should have a few elementary principles combined in the organs in varying proportions.

Etiology of Metasyphilis.—Villinger relates a history which he thinks is able to throw light on this obscure subject. A man of sound stock and health contracted syphilis at 24, and was properly treated. The disease had one period of relapse during the first year. He did not marry until five years after infection, but nevertheless begot a syphilitic child which infected the mother. Eight years after the chancre vague symptoms began to appear which suggested a possible tabes. Within a period of three years these had vanished. These symptoms came on in certain periods with intervals of apparent health. They comprised lightning pains and paresthesiæ on the perineum and genitals; a mild grade of weakness of the urinary bladder; loss of sexual desire, and slight difficulty in articulating. The remissions and final disappearance of the symptoms could hardly have been due to the mercurials and iodides which were given the patient, for these had no immediate influence on their severity. During the entire period of pretabes, there was one other symptom constantly present just before the exacerbations. This was a sense of tension and tenderness in the groins, due apparently to swelling of the already enlarged lymphnodes. The state of the latter had gradually improved when the attacks ceased. The author sees here a possibility that spirochetes latent in the glands had perished and at the same time liberated a highly neurotoxic substance. Virchow used to attribute tertiary lesions to a similar causation. The spirochetes did not proliferate and reach the blood, for had this been the case we should have had ordinary syphilis, not metasyphilis. That the latter was in this instance abortive should be due to the small quantities of toxin liberated. If the author is right, all belated enlarged lymphnodes should be extirpated.

Results of Extirpation of the Hypophysis.—Ascoli and Legnani have been at work on this subject for three years. In growing animals growth was promptly arrested, ossification and dentition were delayed. The nutrition of the bones also suffered so that fragility resulted. The animals as a rule became corpulent and sexual maturity was delayed. The endocrin glands all appeared to suffer, notably the spleen, thymus, thyroid, and suprarenals. They exhibited arrested development and retrograde changes. These symptoms agree with the picture of hypopituitarism in man—dwarfing, adiposogenital dystrophy. So thyroidectomy and thymectomy by causing an arrested development of the hypophysis similarly give rise to symptoms akin to hypopituitarism.

March 7, 1912.

Disorders of Gastric Motility.—Borgbjarg states that disorders of motility exceed in importance those of secretion. To study these he prefers Faber's modification of Bourget's test meal which consists of 250 cubic centimeters oatmeal soup, 50 grams minced boiled meat, 50 grams white bread and butter, eight boiled plums and one dessertspoonful of cranberry preserve. If a minimum of 10 cubic centimeters residue of this meal is found in the stomach after a given period, say eight hours, one speaks of an eight-hour retention. A twelve-hour retention is synonymous with persistent retention, and is due to organic obstruction at the pylorus or pylorospasm, the latter due usually to the presence of an ulcer. A five or six-hour retention usually means cancer, ulcer, or gastritis, but sometimes has a functional cause which can be determined by chemical analysis. This degree of retention, however, may be due purely to atony, gastroptosis, or even an intestinal anomaly. In some instances prolonged retention does not mean persistent retention. The presence in the stomach merely of the indigestible residue of the plums, berries, meat, etc., usually means an organic stomach lesion. If nothing serious is found and constipation coexists, a five or six-hour retention indicates a well-ballasted diet. A bland diet often cures motor insufficiency from weakness of the gastroenteric tract. In poorly nourished patients an overfeeding diet often overcomes this weakness.

Determination of the Resistance of the Erythrocytes.—Von Liebermann and von Fillinger describe a technical procedure and the results obtained therewith from which they conclude that a ½ per cent. solution of sodium chloride does not cause hemolysis in the blood of a healthy subject or does so in traces only. There are, however, certain diseases and states of weakness in which the normal resistance of the cells is not weakened, so that no criterion of health or ill-health is forthcoming here while conversely there is sometimes found a diminished resistance where there has been no reason to suspect such. The resistance is also reduced in various morbid conditions, but not in such a manner as to throw light on the nature of the underlying cause. Generally speaking, the more protracted the disease, the greater the elements of anemia and debility, the more constant and pronounced the lowering of the erythrocytic resistance. The reaction is a debility reaction. Certain poisons produce the same effect and may produce it rapidly. Alcohol is such a poison. The method consists in taking a drop of the suspected blood and exposing it for two minutes to 5 cubic centimeters of a ½ per cent. solution of NaCl, shaking gently, and then using the centrifuge. If the supernatant fluid is clear resistance is normal.

Success of Antiserum Treatment of Dysentery.—According to Krause the results recently obtained with serotherapy in the Shiga type of dysentery in Eastern Austria are fully on a par with those of the antitoxin treatment of diphtheria. He has recently controlled a material of over 2,000 cases during the past year. This could also be contrasted with a large material of cases otherwise treated. The mortality of the cases treated with antiserum was between 9 and 10 per cent., while that of the material otherwise treated was between 19 and 20 per cent. One condition of success was that the serum must be given as early as possible, when its beneficent action was at once evident in the abortive course of the disease. The serum is essentially antitoxic, as it possesses only weak antibacterial powers.

The Specificity of the von Pirquet Reaction.—E. Tezner has found that children who react positively to the cutaneous inoculation with old tuberculin also react in a similar manner to the toxin obtained from the colon bacillus. In these cases there is a negative reaction to the cholera toxin or to peptone. These phenomena are explained as follows. An individual who has been infected with tuberculosis is also hypersusceptible to toxins of bacteria that accompanied the original infecting microorganism.—*Monatsschrift für Kinderheilkunde.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

Height, Measurements and Weight.—The measurements and weight should never be regarded lightly as, in many cases, they hold a very important place in the list of facts and conditions which must be considered in the selection of risks. Accuracy is imperative in order to avoid an injustice to the company or the applicant, as the case may be. Every examiner should, therefore, provide himself with a good tape measure and he should never fail to resort to the scales when meeting the conditions described further on. The best tape measures are those made of steel and the task of measuring the height will be facilitated if they are six feet in length.

A great many faulty measurements are reported to the home offices. Errors will not occur in the findings of this purely mechanical procedure if the following suggestions, which are definite and observed by most examiners of wide experience, are adopted.

Measuring the Height.—The height of the applicant should be determined accurately by measurement and *never estimated*. Many of the scales made for physicians' offices are provided with a device for ascertaining the height, but when this is not available the good old custom will answer of having the subject stand with his back to the wall, preferably on a wooden floor rather than a carpeted one, with some straight object, such as a book or ruler, reaching horizontally from the top of the head to the wall to indicate the proper spot to mark for the height. The height should be taken with the shoes on, as the tables of comparative height and weight are compiled with this addition to the height in mind.

If the applicant is near or beyond the upper limit of normal weight, care should be taken to have him stand erect so that he may be credited with every inch or part thereof he is entitled to. Undue straining or standing upon the balls of the feet should not be allowed; but, on the other hand, some stout individual who has the habit of carrying himself in a more or less stooped position, might jeopardize his chances for obtaining insurance on the plan applied for or even on any plan whatever if the examiner did not prompt him to stand firmly and fairly erect.

Measurements of the Chest and Abdomen.—Accuracy in these measurements is of special importance in the examination of overweights, as so much depends in these cases upon the measurements of the chest compared with those of the abdomen. The frequent discrepancies between the measurements by different examiners of the same subject is a matter of comment at the home offices as indicating a lack of care and uniformity; they may easily be avoided if all examiners adopt a common and approved method.

Always take the measurements on the bare skin. This procedure is easily accomplished if the trunk of the applicant is exposed in the manner described in a preceding chapter, for the examiner may then eliminate the errors arising from including more or less of the clothing. If this precaution is not observed, the measurements of the chest may be made over a thin shirt while that of the abdomen includes a part of the thick trousers and underclothing.

The Chest.—The chest should be measured at the nipple line, the tape measure being carried horizontally around the body.

When the applicant is a woman a measurement at the level of the nipples will not ordinarily be a fair one for two reasons, the thickness of the breast at that point and the lower position on the chest wall occupied by the nipples when the breasts are pendulous. The proper course to pursue in such an instance is to carry the tape measure around the body just high enough to avoid the thick part of the breasts.

Even in the case of a woman it would be better to measure the chest and abdomen next to the bare skin if the applicant is a heavy weight. When, however, there is a woman with a pendulous abdomen to contend with, the examiner may find it impracticable to secure sufficient exposure of the body for him to carry the tape line over the umbilicus next to the bare skin. Therefore, if clothing must be worn, and as both the chest and abdominal measurement should be taken over the same amount of clothing, the applicant should properly prepare herself for the examination by wearing a loose flowing gown of thin, light material.

Examiners will not infrequently meet large, lusty fellows who are unable to show an expansion of more than half an inch or an inch notwithstanding strong but futile efforts. The same individuals will usually gain an inch or more of expansion without undue exertion after a bit of coaching. It is especially desirable to get all the expansion the applicant is capable of in overweights, as the comparison of the measurement of the expanded chest with that of the abdomen may exert a strong influence on the final action at the home office. Examiners are often asked to remeasure the applicant and it is a common experience for them to find that they did not succeed in getting a full expansion the first time. The significance of these measurements will be more fully discussed later under the subject of "overweights" as a class.

The Abdomen.—More errors take place in measurements of the abdomen than in any of the others. This lack of accuracy, while of little consequence in the case of normal abdomens, gives rise to much trouble and extra correspondence when the applications of overweights are under consideration. Special attention is directed to the following suggestions:

First—The abdominal measurement should always include the umbilicus. The application blanks should call for this, and in the few which only mention the waist line it is probably assumed that the instructions apply only when the navel is in its proper location. As a matter of fact, the abdomens so unpopular at the home offices are those loaded with an accumulation of fat as a result of which they are apt to be pendulous with the umbilicus well below the waist line and on a level with the upper part of the buttocks.

Second—The buttocks and the crests of the ilia should *never* be included in the abdominal measurement. Failure to observe this precaution is a too frequent occurrence and leads to the reporting of a measurement far in excess of the true one, even in fat subjects.

Third—The rule for measuring in a horizontal line will have to be departed from when dealing with a pendulous abdomen which has carried the umbilicus below the level of the crests of the ilia. In these cases the tape line should be carried obliquely

from a point on the back just high enough to escape the crests and low enough in front to reach the navel. In other words, the fat applicant with a pendulous belly must quite properly pay a penalty by having his abdominal measurement taken in an oblique line. When it is necessary to resort to this plan of measurement the examiner should mention it in his report.

Fourth—All chest and abdominal measurements of heavy weights should be taken next to the bare skin in order that the comparison in these cases may be based on accurate figures.

Fifth—Women are apt to have pendulous abdomens after pregnancy. In such cases two measurements should be taken; one horizontally at the waist line, and the other in an oblique direction from a point on the back high enough for the tape-line to escape the iliac crests and low enough in front to include the umbilicus. Both measurements and the reason for taking them should be clearly described in the report, as a penalty is not exacted from a woman for having a pendulous abdomen as a result of labor unless there is also an excessive accumulation of fat. If, however, the woman is over the normal limit of weight and the measurement over the umbilicus is partly increased on account of adiposity, this fact should be invariably stated in the report.

It may be difficult to obtain a measurement next to the bare skin when the woman's abdomen is very pendulous on account of the great amount of exposure demanded. In the event of such an applicant being an overweight, she should be previously requested to limit her clothing to a gown of light material, and to especially exclude the many articles of underwear which extend downwards from the waist. Very few women will refuse to prepare themselves properly for the examination if the matter is tactfully and courteously explained to them.

Sixth—When drawing the tape together, use the same degree of tension in taking the chest and abdominal measurements.

Seventh—Some agents will train an applicant to draw in his abdomen while the examiner is trying to measure him. This trick is easily detected and must never be permitted.

Eighth—The possibility of an abdominal tumor or ascites should be kept in mind when an excessive abdominal measurement is encountered. A definite statement as to whether or not one of these conditions exists, or whether the measurement is due to adiposity should be included in the report.

Weight.—The weight should be taken with the ordinary clothing on, including coat and vest, as the figures given in the tables are computed with this extra weight in mind.

The weight should be ascertained by scales whenever possible. Oftentimes, however, no scales will be at hand and under such circumstances the weight must be estimated. When the weight is near the standard the need of actual weighing is not so great; but there should be no doubt in the examiner's mind as to the importance of resorting to the scales when it approaches the neighborhood of or exceeds the limit under or above the standard. It is no easy matter to estimate the weight of heavy people correctly as so much depends on the quality of the tissues, and it is not uncommon for the examiner, who has subsequently been requested to weigh the applicant, to find a weight twenty to fifty pounds more than that given in his estimate in the original report.

An examiner will invariably be requested by the home office to weigh applicants who are near or beyond the limits set forth in the tables, if he has not already done so. It will, therefore, save time and correspondence if he attends to this requirement in the first place.

Wassermann Reaction in Judging a Claim for Indemnity.—Hoffman tells of an applicant for indemnity who claimed to have developed tabes dorsalis in consequence of a severe accident. He denied luetic infection absolutely and showed no physical signs of the disease; his wife, however, has had several miscarriages. He was examined several years ago and at the time indemnity was granted as the rôle of trauma in the development of tabes could not be denied. In 1910 the patient was reexamined and this time a Wassermann reaction was done and proved to be positive. Physical signs of syphilis were, however, still absent. It was the opinion of the expert examiner that this reaction spoke very strongly for syphilis, yet it alone could not be used as an argument for stopping the payment of indemnity. In the present state of our knowledge it was doubtful whether the reaction alone could be depended upon in a case where blind faith in it could work an injustice to the applicant. Moreover, accident may have been the exciting cause of tabes dorsalis in a man with latent syphilis, and his present helpless state may never have occurred without the trauma. The payments were therefore continued.—*Zeitschrift für Medizinalbeamte*, Vol. 24, No. 17.

A Case of Multiple Sclerosis from Chronic Gas Poisoning?—Dr. Walter Stempel gives a detailed history of a patient who met with an accident resulting in fracture of the leg, and several years later claimed indemnity because of various nervous symptoms, which he referred to the accident. The patient spent these years as a laborer in a gas plant. He showed moderate ataxia, spoke in a monotone, and frequently laughed without cause. His hands trembled markedly especially in reaching for objects and in writing. The deep tendon reflexes were exaggerated. Pupils and eyegrounds were normal. The diagnosis of multiple sclerosis was made on these findings, and the relation between the previous accident and the nervous symptoms were not interpreted as at all causal. Later, the applicant told of having been at one time poisoned with illuminating gas, and this story was corroborated by his fellow workers. He therefore claimed that this accident may have been the cause of the nervous disease he developed, for previous to it he was normal and an ablebodied worker. Finally Dr. Lewin, a noted authority on toxicology in Berin, was asked for an expert opinion on the case. His analysis, which is printed in full by Stempel, shows the possibility of great injury to the nervous system from poisoning with illuminating gas, several such cases having come under his observation. Dr. Lewin's conclusion was that the applicant was entitled to the indemnity claimed. The fact that other laborers employed with the applicant and doing similar work were not affected by the gas was not at all proof positive that they would not have been affected had they been in the same physical circumstances as the patient on the day of the accident. Moreover, it is a well-known fact that a great many workers escape poisoning in some dangerous trade, while fellow workers are affected. Individuality plays a most important rôle in industrial accidents of this nature. —*Zeitschrift für Versicherungsmedizin*, January, 1912.

Book Reviews.

La Responsabilité Atténuée. Lois faites dans les divers pays, lois à faire concernant les criminels à responsabilité atténuée. Par le Docteur L. Mathieu, Rapporteur au III. Congrès International de Médecine Légale (Bruxelles, 1910), Inspecteur des Écoles, etc. Préface de M. Joseph Reinach, député. Price 2 francs. Paris: Vigot Frères, 1911.

In this monograph of 128 pages the author analyzes the doctrine of attentuated responsibility in criminals, traces its historical development, and reviews the attitude with regard to this doctrine of the legal systems of different countries. To the alienist, the medical expert, and the jurist this volume should prove an invaluable contribution on a subject about which very little has been written.

A Handbook of Medical Diagnosis. In Four Parts. I. Medical Diagnosis in General. II. The Methods and Their Immediate Results. III. The Symptoms and Signs. IV. The Clinical Applications. For the Use of Students and Practitioners. By J. C. Wilson, A.M., M.D., Professor of the Practice of Medicine and Clinical Medicine in Jefferson Medical College, and Physician to its Hospital, Physician to the Pennsylvania Hospital, Physician-in-Chief to the German Hospital, Philadelphia. With 418 text illustrations and 14 full-page plates. Third Edition, Thoroughly Revised. "The Whole Art of Medicine is in Observation." Price $6.00. Philadelphia and London: J. B. Lippincott Company, 1911.

That three editions of this work have appeared within a period of less than two years is alone evidence of the fact that it has been well received. The vigilance of the author in seizing upon every new and substantial contribution to medical science is manifested in the present edition by the inclusion of such topics as Brill's disease, which is designated as pseudotyphus. An unusually large amount of material is crowded within the ample 1,438 pages of this book, the preparation of which must have involved considerable labor. Fortunately, an excellent index enables one to make this material available for quick reference, and therefore adapted both for the desk and the laboratory table. Among the alterations in and additions to this edition may be mentioned the rewriting of articles on typhus fever and relapsing fever, on poliomyelitis, beriberi, and pellagara, and the addition of a section on the electrocardiograph. The work is well written and handsomely illustrated, and may be safely recommended as a reliable guide in diagnosis.

Case Histories in Medicine. Illustrating the Diagnosis, Prognosis, and Treatment of Disease. By Richard C. Cabot, M.D., Assistant Professor of Clinical Medicine, Harvard Medical School. Second Edition, Revised and Enlarged. Price $3.00. Boston: W. M. Leonard, 1911.

This volume contains one hundred case histories classified under the following headings: infectious diseases, diseases of the gastrointestinal and biliary tract, diseases of the urinary tract, diseases of the circulation, the respiratory system, the nervous system, diseases of lymphatic and ductless glands, and diseases of unknown origin. The fourth in the case history series, this work, together with its predecessors, amply demonstrates the didactic value of the case history method. The originality and charm which pervade all of Dr. Cabot's writings are strikingly manifested in the present work. The plan pursued is "to make the reader work, to present puzzles like those which confront us at the bedside, and then to offer at the end of each case a solution of these puzzles." The introduction of questions and answers relating to important points in the various cases makes this work a valuable one, not only to undergraduate and postgraduate students, but also to the practitioner. It will undoubtedly continue its wide popularity.

La Fatigue et le Repos. La Fatigue. La Conservation des Forces. Le Médication par le Repos. Par le Dr. Fernand Lagrange, Lauréat de l'Institut. Publié avec le concours de Dr. F. de Grandmaison. Price 6 francs. Paris: Félix Alcan, 1912.

This is a posthumous work of Fernand Lagrange, who for thirty years devoted his attention to the physiology and hygiene of exercise and to the study of the various forms of mechanical movements. The author discusses the physiology and psychology of fatigue, its severe forms, morbid fatigue, the conservation of strength, the precautions to avoid fatigue, relaxation through movement and physical agents, moral recreation, the remedies for fatigue repair through proper regimen, the psychology of training, the conditions of rest and its psychology, the rest suitable for the organs, the rest of the mind, and the rôle of rest in various diseases. The work is a most practical treatise on an important subject.

Handbuch der speziellen Chirurgie des Ohres und der oberen Luftwege. Herausgegeben von Dr. L. Katz, Spezialarzt für Ohren-Nasen-, und Halskrankheiten in Kaiserslautern; Dr. H. Preysing, Prof. der Ohren-Nasen-, Kehlkopfheilkunde, Ord. Mitglied der Akad. für prakt. Medizin zu Cöln a. Rh.; und Dr. F. Blumenfeld, Spezialarzt für Nasen-, Hals-, und Lungenkrankheiten in Wiesbaden. 1 Bd., 1 Hälfte, Lief. 6. Price 3 marks. 1 Bd., 2 Hälfte, Lief. 2/3. Price 9 marks.

The concluding instalment of the first half of the first volume of this monumental work concludes the subject of general anesthesia in the surgery of the upper air passages. Local anesthesia in the surgery of the nose and throat is discussed by P. Heymann, and local anesthesia in aural surgery by O. Voss. Isemer deals with the subject of hyperemia therapy. Life, accident, and health insurance in relation to the surgical conditions of the upper air passages is dealt with by F. Ropke. An index concludes this part of the work. The second and third instalments of the second half of the first volume contain the subject of prothesis, by G. Port. Corrective plastic surgery of the nose and ear is presented by J. Joseph, and paraffin therapy is dealt with by A. E. Stein. P. Bockenheimer takes up the subject of plastic operations. In the thoroughness of the text and in the extraordinary profusion of illustration the two parts that have just been issued maintain the standard that has been set in the earlier issues.

The Practical Medicine Series. Volume X. Nervous and Mental Diseases. Edited by Hugh T. Patrick, M.D., Professor of Neurology in the Chicago Policlinic, Clinical Professor of Nervous Diseases in the Northwestern University Medical School, ex-President Chicago Neurological Society; and Peter Bassoe, M.D., Assistant Professor of Nervous and Mental Diseases, Rush Medical College. Series 1911. Price $1.25. Chicago: The Year Book Publishers.

Four-fifths of this volume are given up to the consideration of nervous diseases and the remaining one fifth to mental diseases. As the title implies, the book covers the literature of the past year on the subjects, and the matter presented is both interesting and valuable.

A Compend of Genito-Urinary Diseases and Syphilis, Including their Surgery and Treatment, by Charles S. Hirsch, M.D. Formerly Assistant in the Genito-Urinary Surgical Department, Jefferson Medical College Hospital; Consulting Physician, Social Service Hospital and Juvenile Protective Association, Philadelphia. Second edition with 74 illustrations. Price $1.25 net. Philadelphia: P. Blakiston's Son & Co., 1912.

In the preface to this edition the author claims that he "has carefully revised the entire work." But it seems to us that this is exactly what he has not done; and, further, we have never seen a book which needed such revision more than this work does. Printers' errors, slipshod statements, misspelled proper names, sentences that defy analysis can be found on almost any and every page. The prescriptions are, of course, loaded with mixtures of English and barbarous Latin; in most instances the author has not even taken the trouble to correct the errors which were in the first edition. From preface to index the book should be thoroughly overhauled before medical students and practitioners are invited to purchase it.

Sight Testing for the General Practitioner. A Manual by which he can acquire the knowledge necessary to determine all errors of refraction and to prescribe spectacles. By F. Davidson. Price 2/6 net. London: F. Davidson, 29 Gt. Portland Street W., 1912.

This little volume of 82 pages purports to give all that is necessary to enable the student to obtain a working knowledge of refraction. It begins with the consideration of the principles of optics; a few pages are then devoted to the consideration of hypermetropia, myopia, accommodation, presbyopia and astigmatism as regards the anatomical conditions necessary for the production of these errors of refraction. The rest of the volume is devoted to the consideration of the tests necessary for determining the correction of these conditions and the consideration of the anomalies of the muscles. It is a useful book for one who wishes to obtain merely a working knowledge of the subject.

Periodizität und periodische Geistesstörungen. Von Dr. Franz Mugdan, Freiburg i. B. Price 0.75 mark. Halle a. S.: Carl Marhold Verlagsbuchhandlung, 1911.

In this essay of eighteen pages there is presented a philosophical analysis of periodicity and periodic insanities. The author defines periodicity as follows: "It is a property of a series of logically related phenomena that recur at definite intervals as the result of causes that are inherent in the individual affected, and that are dependent for their production on no outside factors or influences."

The Practical Medicine Series. Volume IX. Skin and Venereal Diseases, Miscellaneous Topics. Edited by W. L. Baum, M.D., and Harold N. Moyer, M.D. Series 1911. Price $1.25. Chicago: The Year Book Publishers.

This volume is divided into two sections. The first deals with skin and venereal diseases, the second with miscellaneous subjects, such as History of Medicine, Insurance, Medicolegal Questions, and Sociology. The publication maintains the standard established by the previous volumes of the series.

Principles and Practice of Physical Diagnosis. By John C. DaCosta, Jr., M.D., Assistant Professor of Clinical Medicine, Jefferson Medical College; Assistant Visiting Physician, Jefferson Hospital; Hematologist, German Hospital; Fellow of the College of Physicians of Philadelphia; Associate Member of the Association of American Physicians, etc., etc. With 225 Original Illustrations. Second Edition, thoroughly revised. Price $3.50. Philadelphia and London: W. B. Saunders Company, 1911.

This volume is a well-written book of over five hundred pages, in which the methods and scope of physical diagnosis are considered under five sub-headings, namely, methods and technique of physical examination, examination of the thorax, examination of the bronchopulmonary system, diseases of the bronchopulmonary system and mediastinum, examination of the cardiovascular system, diseases of the cardiovascular system and examination of the abdomen and the abdominal viscera. Normal physical signs are thoroughly discussed, so as to adapt the work to the needs of even junior students; on the other hand, diagnostic points are entered into with a completeness that should satisfy senior students and practitioners of medicine. The new edition shows much new matter, especially in the subjects of sphygmomanometry, pleurisy, etc. The volume is primarily a textbook, and, compared to others on the same subject, is a good one.

The Accessory Sinuses of the Nose in Children. One Hundred and two specimens reproduced in natural size from photographs. By Prof. A. Onodi, Director of the University Clinic for Diseases of the Nose and Throat in Budapest, with a Preface by Prof. W. Waldeyer, Director of the Anatomical Institute of the University of Berlin. Translated by Dr. Carl Pransnitz, Hygienic Institute, University of Breslau. Price $7.00. New York: William Wood & Co., 1911.

This is truly a classical atlas. Commenting on the incompleteness of our knowledge of the nasal sinuses in children the author has presented a series of beautifully executed plates of specimens cut with a fret-saw in coronal, longitudinal, and horizontal planes, and then accurately photographed. The specimens are from the fetus and from children of various ages up to nineteen years. Accompanying each plate is a description in German, French, and English. Preceding the plates is a brief description of the various sinuses from their first appearance until after the beginning of puberty. This section of the work occupies twenty-three pages, and then follow the plates. Professor Onodi displays a most intimate acquaintance with the literature of sinus diseases and writes with the modest confidence of the true scholar. No rhinologist can afford to omit this book from the shelves of his library.

The Treatment of Fractures by Mobilization and Massage. By James B. Mennell, M.D., B.C., Cantab, etc. Late Resident Medical Officer of St. Thomas's House; House Surgeon, Casualty Assistant and Clinical Assistant to Physical Exercise Department, St. Thomas' Hospital. With an introduction by Dr. J. Lucas-Championnière, Chirurgien Honoraire de L'Hôtel Dieu, Membre de l'Académie de Médecine, Président de la Société Internationale de Chirurgie, etc. Price, $4.00. London: Macmillan & Co., 1911.

The book is an exposition of Lucas-Championnière's principles of treating fracture by massage and mobilization. He contends that the surgeon can and should obtain better results than by immobilization. The author, who is an enthusiastic supporter of this treatment, calls our attention to the pessimistic feeling regarding the current methods of treating fractures, as evidenced by Lane's expression: "The treatment of fractures, as it exists at the present, is a disgrace to surgical practice." Mennell feels that many of the failures can be avoided by the proper use of massage and mobilization. The reason that this method has not advanced in England is due to the fact that the nature of the massage and the regulation of the mobilization is not understood. It is not the massage of the professional masseur, but a slow, gentle, rhythmical repetition of a single movement, performed with a uniform speed and monotonous regularity; any movements across the axis of the muscle are useless and dangerous; the cessation of the pain indicates that the massage has been correctly applied. The author explains what is meant by mobilization, thus removing many common misapprehensions concerning the method. The treatment of the individual fractures is clearly described, and with the aid of the accompanying illustration, no difficulty should be experienced in carrying it out. The following is a summary of the treatment advocated: Restore the fragments to their original positions; the most efficient means, short of an open operation, are massage and mobilization; the long axis of the fragments must remain parallel; perfect reduction, short of an operation, is rare; complete restoration of function is the criterion of treatment rather than perfect structural restoration. Operation is indicated in the following conditions: Gross deformity, deformity interfering with the function of the limb, persistent deviation of the axis, and when shortening is a disadvantage to the patient. The work is the most satisfactory exposition of the Lucas-Championnière methods in English.

Meine Blutuntersuchungen. Von E. v. Behring, Marburg. Price 6 marks. Berlin: Verlag von August Hirschwald, 1912.

This is a small monograph on the technical subject of estimating the total quantity of blood in an animal by means of injecting a toxin, and then calculating the amount of antitoxin produced. It contains accounts of numerous experiments with the method, complete data being given, so that the volume should prove useful to other workers in the field. The reviewer is inclined to quarrel with the title, which is indefinite enough to suggest that the monograph deals with more general laboratory hematology and not with the very special subject above indicated.

Étude sur les Fractures de l'Extrémité Inférieure de l'Humérus chez l'Enfant. (Résultats Éloignés.) Par le Docteur André Trèves, Ancien Interne des Hôpitaux de Paris et de la Clinique Chirurgicale Infantile de la Faculté; Assistant de Chirurgie Orthopédique à l'Hôpital des Enfants-Malades, Membre Adjoint de la Société Anatomique. Price 10 frs. Paris: G. Steinheil, 1911.

This monograph is a contribution to the literature of the surgery of children. It is a study of the late anatomical and clinical results in fractures of the lower extremity of the humerus. The book is divided into three parts: Supracondyloid fractures; fractures of the external condyle; and epitrochlear fractures. Each section contains chapters devoted to the pathology, the treatment, and the end results of these fractures; accompanying the numerous case reports are drawings made from the radiographs. The author states that in children the most fractures occur between the ages of 5 and 10; the commonest fracture is the supracondylar; in 325 elbow injuries 153 were supracondylar. Immobilization in flexion (Jones' position) is advocated for this fracture, the position being retained by means of a circular plaster bandage, or after the manner of Scudder and Lusk. Trèves considers passive mobilization and massage impracticable; reduction by extension complicated, and operative interference rarely necessary. The treatment of the epicondylar fractures is as a rule very simple, on the other hand treatment of fractures of the internal condyle presents greater difficulties than supracondylar fractures. The increased difficulty of reduction may call for operative interference. From a clinical and anatomical study Trèves concludes that fractures of the elbow have a better prognosis than has been attributed to them; in 163 cases of fractures of the lower end of humerus 4 presented a bad result, 12 a passable result, and the remainder were almost perfect cures. He is strongly opposed to operative interference, and holds that early operation should be reserved for irreducible luxations and compound fractures accompanied by certain nervous lesions. In the later operations for vicious callus, nervous lesions, etc., the simplest and least mutilating operations are the best.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, Held March 7, 1912.

THE PRESIDENT, DR. WM. M. POLK, IN THE CHAIR.

The Accomplishments and Possibilities of Medicine in China.—Dr. EDWARD H. HUME, Field Secretary of the Yale College in China, made this address, which was accompanied with an interesting lantern slide demonstration. The conditions attending medical practice in China were very similar in many respects to those in Asia Minor and other non-Christian countries.

Medical Missionary Work in Asia Minor.—DR. WILFRED M. POST, of the American Hospital, Konia, Turkey, read this paper, in which he showed the need of medical missionary work in Turkey, illustrating his remarks by lantern slides. He reviewed the political events that had transpired during the past four years and summed up the present condition of Turkey in the remark of Riza Nour Bey, a deputy of the Turkish Parliament, "Our country has long been suffering from latent tuberculosis, and now it has reached the stage of galloping consumption." In the extremity of the empire lay the supreme opportunity of foreign missions. In Asia Minor most of the missionary work was being done by Americans, and it included printing and distributing the scriptures and other literature in the various languages of the empire, education, both lower and higher, Y. M. C. A. work, industrial training, and medical work. The ministry of healing in Asia Minor had its beginning with the work of Florence Nightingale, who went to Crimea in 1853 and took charge of the hospital at Scutari. The first regular medical missionary work was begun in 1859, when Dr. Henry West went to Sivas. In addition to practising among the people he trained a class of native students who went into practice and became known as the most reliable medical men in their generation in Asia Minor. In 1867 the medical department of the Syrian Protestant College, an American missionary institution, was established in Beirut, Syria, and Dr. Post's father, the son of Dr. Alfred C. Post, who was president of the New York Academy of Medicine in 1867 and 1868, was called to it. The influence of this growing medical school had been felt all over the Turkish Empire. Later the French Jesuits established a medical school at Beirut and there was also a government medical school in Scutari. These were the only regular institutions for training physicians for the whole empire of thirty or forty million inhabitants. In Smyrna and Constantinople there were, of course, several hospitals and the government had established a hospital in Broussa and another in Afion Kara Hissar. There was a large uncared for region, larger than New York State, in which there was no hospital or no medical work of any kind, either governmental or missionary. In some of the larger towns of the eastern part of Asia Minor there were centers of medical missionary work and a few local government hospitals scarcely worthy of the name, being merely khans or inns where a few of the city poor were housed, and in which little or nothing of modern surgical methods was known or practised. In most of these centers there were but one American physician and one or two trained nurses. Dr. Post said that he had gone to Turkey in 1904, and for six years had worked in Cesarea; last spring they had opened a new work in the large region which had been referred to. The medical missionary was not allowed to enter Turkey until he had passed an examination in Constantinople before the government medical authorities, either in French or in Turkish. Dr. Post described his trip from Constantinople to the interior and exhibited pictures showing the poverty and need of the country. They saw almost all of the diseases of the United States in Asia Minor, but often greatly aggravated, and with others superadded. Eye diseases were very common, especially trachoma, and keratitis and entropion resulting from it. Many cases of cataract came to them, and in a village near the Turco-Persian border the art of operating on these cataracts had been handed down from father to son. Their method of operating was to have the patient held on the ground and then to hold the eye open and plunge a long, sharp thorn into the corneoscleral juncture so as to catch the edge of the lens and depress it downward and away from the pupil into the vitreous. The patient usually saw for an instant and then his eyes were bandaged and he was put on a strict diet for forty days. Of course the vast majority of eyes were destroyed by this procedure. Hernia was extremely common and was treated by applying poultices and buffalo manure to the top of the head. A black chicken with yellow legs was hung about the neck for the cure of jaundice until the [illegible] softened." Suppurative adenitis of the neck was called "mole," and was treated by feeding the patient cooked mole. Fractures were frequently bound up so tightly that gangrene and death ensued. The burden of the suffering fell most heavily on the women, who came in the most pitiful condition to the missionaries. The native midwives used the knife recklessly in difficult labor and the practise gave rise to enormous fistulæ. Syphilis was common in the interior of Turkey, and there were towns where perhaps 50 per cent. of the population were infected. Leprosy was also common, but was seldom seen in the aggravated tropical forms. Malaria was everywhere, and epidemics of cholera, typhus fever, typhoid fever, and smallpox appeared from time to time. The ignorance and fatalism of the people made it difficult to cope with these epidemics. Patients came to them from great distances—four, six, eight, or even ten days' journey—in carriages, on horseback, in ox carts, and sometimes a man would even carry his wife to the clinic on his back. Their hospital workers were both native and foreign. Nurses were given a course of training as full as they could make it and most of the native ones were recruited from the missions. Dr. Post described their temporary quarters in Konia, a city of 70,000 inhabitants, the center of the vast district before spoken of as destitute of medical work. They had now planned a hospital which would accommodate 100 patients, which was a comparatively small number when one thought of the great field to be covered. Speaking of the financial side of the work Dr. Post said that for the year 1908-1909 the total budget for running their hospital of forty beds at Cesarea was about $12,000; this covering the salaries of medical missionaries, trained nurses, native physician, druggist, druggist's assistant, native nurses, helpers, and servants, together with the outlay for drugs, surgical instruments, etc. During that time they had 410 patients in the hospital, 6,206 out-patients, and performed 708 operations. They made patients pay when they could, and from this source they took in $7,000, which went toward defraying the expenses of the hospital, leaving $5,000 to be paid from American funds. Their work was by no means confined to the hospital and dispensary, for they were often called to make tours lasting weeks or months. They endeavored to make some medical missionary tours every year, staying in towns a month or six weeks and practising among the people. Dr. Post described a visit to one of these towns never before visited by a missionary and told of the difficulties encountered among a people taught from infancy to despise a Christian, and how these people eventually came to them and when they went away gave them an invitation to return again. Great was the need, the speaker said, and great also was the opportunity which confronted the medical missionary in Turkey today.

Untouched Fields in the Medical Profession.—MR. ROBERT E. SPEER delivered an address on this subject. He laid emphasis upon the fact that there should be no racial division. In the first place, there was the great mass of people who were suffering and who lived outside the western civilization. For instance, in Persia, where there were 9,000,000 people, there were but thirty doctors who had skilled training; in Korea, with a population of 12,000,000 people, there were only thirty-six doctors who had skilled training; in China there were something like 350,000,000 people, and they had but 365 medical missionaries. In India 80 per cent. of the population lived in villages and 85 per cent. of the doctors lived in the cities. In Chili 80 per cent. of the children died before they reached the age of two years, and here they had one physician to every 3,225 of the population. In Bolivia there was one physician to every 10,000 of the population. In South America there was not a competent physician to attend a 5,000,000 Indian population. In the United States there was about one qualified physician to 600 population. In the second place was to be considered preventive medicine, and here they had to contend with ignorance and superstition. He called attention to the great epidemics of diseases that had occurred in Asia, and especially to the fact that 80 per cent. of the children born in the province of Chili, in Northern China, died before arriving at the age of two years, an awful and frightful waste of life. There was an immense field in Asia, as well, for men who wished to go and help in the prevention of this frightful mortality. In the third place there was that apparently hopeless class of cases, the insane, the blind, the mute and the deaf, as well as the tuberculous. In the fourth place there was a call for medical men of the western civilization. There was no medical school in the Chinese empire except those that the medical missionaries had established.

SECTION ON SURGERY.

Stated Meeting, Held March 1, 1912.

DR. FRED. H. ALBEE, CHAIRMAN PRO TEM.

Chronic Empyema (Delorme).—Dr. CHARLES E. FARR presented two patients. The first was a child two and a quarter years of age whom he had seen first last June. She was very anemic and had a discharging sinus which had persisted for fifteen months. There was no chest deformity. He resected the sixth and seventh ribs and found a cavity of considerable size. The child only remained in the hospital two weeks and made a perfect recovery. The second patient was a lady who had a streptococcus infection following childbirth some two years ago. It was thought at first that she had tuberculosis. Signs of empyema on the left side soon appeared. She was operated upon and the sixth, seventh, and eighth ribs were removed. There was found a very large cavity which was partly empty. The resulting sinus healed within one month and now she was in splendid condition. He was able to decorticate the ribs without any trouble. She was now in absolutely perfect health.

A Case of Bone Transplantation for Pseudoarthritis of the Tibia and Fibula.—Dr. FRED H. ALBEE presented a man who had been in an automobile accident in April last in Scotland. He was unconscious for one hour after receiving a bad injury which resulted in deformity to his foot. The metatarsal bones were dislocated outward. For ten months he was unable to use the foot. He was given the Bier hyperemia treatment at the Royal Infirmary at Edinburgh. The *x*-ray plates were shown. In these cases the intermedullary splint of Elsberg should be used, and often the results were very satisfactory. Dr. Albee gave a blackboard demonstration of the work that was done in this bone transplantation. There followed firm union.

Total Extirpation of the Tongue for Carcinoma.—Dr. CHARLES A. ELSBERG presented this patient. The patient could now talk coherently and had almost completely the normal sense of taste.

Laminectomy for Spinal Tumors.—Dr. CHARLES A. ELSBERG presented two patients to illustrate the subject of his paper which followed.

Traumatic Cyst of the Pancreas.—Dr. ARCHIBALD E. ISAACS reported this case. The patient, a boy seventeen years of age, was admitted to the Beth Israel Hospital with the diagnosis of empyema of the gall-bladder. He had been well up to six weeks before his admission. At that time he received a severe injury by running against the side of a horizontal bar while exercising in a gymnasium. He lost his breath for a few minutes, broke into a profuse sweat, and vomited for about twenty minutes after the accident. He was then taken to Roosevelt Hospital, where he suffered severe abdominal pains for several days; these gradually left him and he was soon discharged feeling comparatively well after a stay there of ten days. During the five weeks after leaving the hospital he had had three attacks of severe pain, which was referred to the right hypochondrium and to the back in the region of the right scapula. There was nausea, but no vomiting, chills, fever, or jaundice. There was tenderness and rigidity in the right upper quadrant of the abdomen. The temperature was 100.5° F. and the pulse ranged between 80 and 90. Through a right rectus incision the transverse colon presented and a large, hard mass would be felt posterior to it. On raising the colon an area of adhesions was found between the under surface of the mesocolon and this retroperitoneal mass. There was then exposed an angry and almost gangrenous looking surface with areas of fat necrosis in it. An incision into this mass opened into a cavity from which large quantities of clear fluid discharged. About four ounces of a clear fluid were discharged which left a deposit of crystals on the surface of the gauze pads into which it soaked. By a mishap the specimen of fluid was lost. There was a normal gall-bladder, and the foramen of Winslow was open. The duodenum was pulled down and partially kinked by some well-organized bands stretching from it to the transverse colon. The appendix was also kinked by bands and the distal portion was so distended and adherent that decapsulation was required to remove it. While there was no probable connection between the duodenal and appendiceal conditions and the pancreatitis, it was interesting to note that the former must have existed for some time without causing symptoms. A cigarette drain was passed into the cyst cavity; the patient left the hospital, with the sinus closed, twenty-four days after the operation, and has been well since.

Experiences with Laminectomy.—Dr. CHARLES A. ELSBERG read this paper, which was based on his experience with fifty spinal operations performed in two years. He said that it was surprising that so little had been done in spinal surgery, in which the field was very promising, and a much larger number of good results could be obtained than in brain surgery. The dangers from the operation were not great, and after some experience the mortality would be very low. It was a mistake, however, to operate for extensive malignant disease of the arches of the vertebræ, and the spinal muscles usually contraindicated a laminectomy no matter how marked the symptoms of pressure on the cord. Recent fractures of the spine with signs of serious injury to the spinal cord, resulting in complete muscular and sensory paraplegia, especially in the cervical and upper dorsal region, should rarely be subjected to operation. In arriving at the real mortality of the operation of laminectomy cases of this kind should be excluded from the statistics. In forty-four successive operations which the writer had done he had lost but two patients, a mortality of 4½ per cent. Both of these patients were in a hopeless condition, as was shown by the autopsies. In a number of cases in which a tumor was suspected, but none was found at operation, remarkable changes occurred in the symptoms and signs after the operation, giving the distinct impression that the free removal of spinous processes and laminæ with opening of the dura had a very pronounced effect upon the spinal cord. In a paper on this subject by the writer and Dr. Bailey they had reported seven cases in which the patients were markedly improved for a time or entirely freed from their symptoms by the wide removal of spines and laminæ and opening of the dura. There seemed to be no satisfactory explanation for this effect. He had operated upon five patients who had very large tumors of the conus and roots of the cauda equina. Their symptoms were very similar. For several years they had had pain in the small of the back, later absence of knee jerk, the drop-foot, absence of ankle-jerk, pain and stiffness in the lower extremities, slight bladder disturbances, slight and irregular sensory disturbances in the lower extremities. The lower part of the spinal column was held rigid. At operation the lower part of the spinal canal was found to be filled with a brownish-red tumor mass which enveloped the roots of the cauda equina. These tumors were often so large that six or seven spines had to be removed. These growths were reported by the pathologist as being endothelioma or endothelial sarcoma. Their removal was more or less satisfactorily accomplished in two stages. All of the patients recovered from the operation. There was no more satisfactory operation from the standpoint of therapeutic results than the removal of an extramedullary tumor of the cord. Cases of localized intramedullary tumors were more interesting and more rare, and the author expressed the belief that the removal of these tumors from within the substance of the spinal cord was perfectly possible and that satisfactory results could be obtained in this new field. He had operated upon a number of patients with intramedullary disease of the spinal cord, four cases of tumor in the cord, and two of cysts within the substance of the cord, one case of syringomyelia, and one of large cavity formation. In all of these cases, by a special technique and in carefully selected situations, he had made a shorter or longer incision in the posterior median fissure of the posterior column, and in several of the patients the results had been very striking, if not remarkable. The cases of intramedullary tumor had been treated by the method of extrusion. This field of intramedullary spinal surgery was a new one, and there was a great future for this branch of surgery. Among the most satisfactory spinal operations were those for old fracture or injury of the spine. He had operated upon four patients each of whom had had, many years before, an injury to the spine which eventually produced signs of compression of the cord, in some of the patients going on to more or less complete paraplegia. *X*-ray plates showed marked deformities of the vertebræ. The operation consisted of the wide removal of the spinous processes and laminæ over the affected region, with opening of the dura. In all of the patients there was considerable angulation of the cord. The improvement which occurred in all of the patients was very rapid, sensory disturbances diminished, motor power soon returned, and the patients were able to leave their beds and walk again. Among the very rare conditions which the author had encountered was that found in a boy who fell from a scaffolding but who felt no ill effects from the fall until a year later, when he began to have pain with increasing weakness in the lower extremities. When admitted to Dr. Bailey's service he had a complete spastic paraplegia with marked loss of sensa-

tion of touch and temperature in both extremities. He also had considerable bladder disturbance. The peculiarity in his case was the great variability in the amount and degree of his symptoms. The operation revealed the cause of this variability, for he had a varicose aneurysm of the posterior spinal vessels. The main vessels which supplied the aneurysm were ligated and a part of the aneurysm was removed. The boy was making a rapid recovery, the lower limbs improving steadily, and the sensation returning. This operation was done less than six weeks before. The author had been unable to find the report of a similar case in the literature. The operation of laminectomy was preferable to hemilaminectomy; the latter operation required a longer time and was not nearly so satisfactory. It made no appreciable difference to the future function of the spinal column that a number of spinous processes and laminæ had been removed, as the main support came from the bodies of the vertebræ. If the proper instruments were used the exposure and removal of three or four of the spinous processes and the laminæ should rarely take more than ten or fifteen minutes. The skin incision in the mid-line was rapidly made, and the muscles were separated from the spinous processes and laminæ with knife and straight elevator with a sharp edge, bleeding being easily controlled with hot gauze packings wrung out of hot saline solution. With one bite of a large Horsley spine forceps or a giant rongeur the spinous processes were bitten away at their bases. Then with a few bites of a curved rongeur forceps the laminæ were removed on each side and the wound thoroughly dried with sponges over the area of the exposed dura.

Injuries of the Pancreas and Their Surgical Treatment.—Dr. H. FISCHER read this paper. He first related the history of a patient, a girl six years of age, who was struck by an automobile in the left hypochondrium and lumbar region. She was brought to the German Hospital on the day following the accident and upon examination the abdomen was found markedly distended, especially in the region of the epigastrium, less so in the lower parts. The abdominal muscles were rigid, especially in the epigastrium. The greatest point of tenderness was toward the left and a little above the umbilicus. There was some dullness in the dependent parts of the abdomen which disappeared on changing the position of the patient. On the left side, between the lower border of the ribs and the anterior superior spine there was a bloody discoloration of the skin. The pulse was 132, respiration 40, and temperature 99.6°. The urine showed a faint trace of albumin and a few hyaline casts, but no blood, either macroscopically or microscopically. The child had vomited clear yellow fluid. A diagnosis of probable internal hemorrhage was made and a laparotomy was advised; the operation was performed about twenty-four hours after the injury. On opening the abdomen a considerable quantity of dark fluid escaped. The organs all seemed normal, but the omentum showed a multitude of small yellowish-white spots of fat necrosis. The omentum with the transverse colon were turned up to expose the pancreas. The retroperitoneal fatty tissue in the neighborhood of the pancreas showed quite extensive fat necrosis. After the pancreas was fully exposed it was found that the tail of the pancreas was crushed. It was infiltrated with dark blood and softened. The head of the gland was found uninjured. The abdominal cavity was carefully washed out with a large amount of saline solution and a tampon, adjusted around the injured portion of the pancreas, led out through the abdominal incision and the latter was partly closed. The condition of the patient was rather poor until the third day, when she began to improve, and from that time she made a good recovery. A search of the literature revealed only forty-one cases of injury to the pancreas without involvement of any other organ. This was readily explained by the well-protected situation of the gland. Only two cases of injury to the pancreas by bullet or knife had been reported, but injuries caused by blunt force had occurred more frequently. The injuries thus inflicted showed either a complete tear of the gland or a bruising and crushing. Injuries of the head and body were more serious than those of the tail. In injuries of the head the common bile duct might be lacerated, and if the omentum and the gastro-colic ligament were torn the pancreatic secretions had access to the general peritoneal cavity acting injuriously on the tissues; when this happened widespread fat necrosis was seen over the upper part of the abdomen, in the greater and lesser omentum, the mesentery, and the retroperitoneal fatty tissue. This might be so extensive as to cause the patient to succumb. If the patient withstood this first onslaught he might still die of sepsis following the development of retroperitoneal abscess. The recognition of this fat necrosis was of great importance, as it was always present if from twelve to twenty-four hours had elapsed since the injury. If the patient came to operation immediately this symptom might be missing. When no other reason was found for the presence of hemorrhagic fluid it became imperative to inspect the pancreas. The hemorrhage was not usually marked, but it was imperative to protect the peritoneum from the pancreatic ferments. If the injuries were not severe a large hemorrhagic cyst sometimes developed behind the stomach; these cases usually ran a milder clinical course and gave a more favorable prognosis than the former ones. The diagnosis of injury to the pancreas was extremely difficult and in the majority of cases was made only on the operating table. The symptoms were those of peritonitis, which might have been caused by injury of almost any organ in the upper part of the abdomen. There was usually loss of consciousness, with some vomiting of bloody fluid right after the accident. There was then frequently an interval free from pain or distress, followed a few hours later by recurrence of the pain and vomiting. This free interval had been pointed to by Kaerte and Garre as a possible means of differential diagnosis, but the same symptom might be found in rupture of the stomach or gall-bladder. One condition only made the diagnosis fairly certain, and that was the presence of a cystic mass in the upper part of the abdomen, which could be recognized by its relation to surrounding structures. The leucocyte count was usually high. This was true in the case reported. It was incumbent upon the careful surgeon to exclude the possibility of dangerous injury by means of an early exploratory laparotomy. He who waited for clinical symptoms would come too late in a good many cases. The treatment, therefore, was early operation. As long as the splenic artery had not been torn, the blood supply of the tail of the gland was not seriously interfered with, but if the splenic artery had been injured and it was necessary to tie it the separated piece of the gland had better be excised. In cases where the pancreas was crushed and bruised the simplest and best method was the careful adjustment of a tampon around the wounded part, in order to establish free exit for the pancreatic secretions. The pancreas was best reached either by tearing through the loose omentum and entering the lesser sac of the peritoneum or by making one's way through layers of the gastrocolic ligament. Hadra recommended closing the hole in the gastrocolic ligament and making a counter incision in the back. The first method could be effected more quickly and had given good results. If the gland was sutured drainage should always be used. Where there was a complete tear or extensive crushing of the pancreas the secretion of pancreatic ferments might be very abundant—and cause extensive and annoying eczema of the skin around the abdominal wound. Wohlgemuth advised a strict antidiabetic diet which had given very gratifying results in a number of cases. The prognosis of injuries to the pancreas was always grave, and patients who had not been operated on had all died of peritonitis. In cases operated on within the first twenty-four hours the prognosis was much better. In the 42 cases collected five were not operated on, and died. Of 31 which came to operation, 21 were cured and 10 died shortly after the operation; this gave about 60 per cent. of recoveries.

Dr. WILLIAM HENRY LUCKETT said that there was one thing that had not been mentioned, namely, the proneness of all the wounds breaking down after an injury to the pancreas, for catgut and even cromacized catgut would disappear in these cases absolutely within twenty-four hours. This was without doubt due to the action of the secretions from the pancreas.

Dr. ARTHUR S. VOSBURGH reported a case of acute pancreatitis in a woman who gave a history of symptoms of only three days' duration. She was in the childbearing period and had gone six weeks without having menstruated. A diagnosis of ectopic gestation was made. When he first saw her she was lying with her knees drawn up and she complained of pain in the lower part of her abdomen. There was rigidity of the abdominal wall, apparently due to a beginning peritonitis. The diagnosis, in fact, was not made until the abdomen was opened. There was present a fat necrosis which they were unable to recognize under electric light. However, there were soon discovered white spots, which pointed to a pancreatitis. Most of the members of the house staff thought they were dealing with a tuberculous peritonitis until the pathologist's report was sent in. The gall-bladder was carefully explored, as well as the foramen of Winslow, for stones, but none were found. In the absence of gross lesions it did not seem wise to institute any drainage. It was at present eight days since the operation, and the subsequent course of the case should be very instructive.

The pulse ranged from 150 to 160 and the respirations about 55, and she certainly looked like a very sick woman.

Dr. MARTIN W. WARE said that it was difficult to make a positive diagnosis in these cases and referred to Dr. F. Tilden Brown's statement, made many years ago, in which he stated the difficulties encountered. This statement was made at the time he presented to the society a case of fat necrosis. However, one should not throw up his hands and say he was not able to make a diagnosis of these cases.

Dr. CHARLES A. ELSBERG said that two years ago he twice made a diagnosis of acute pancreatitis. There were present symptoms of an acute cholecystitis with an obstruction of the ducts of the liver, a definite area of tenderness, with pain on the left side. Operation proved that his diagnosis in both the cases was correct.

Specimen from Old Ununited Fracture of the Neck of the Femur.—Dr. CHARLES E. FARR presented this specimen. The patient from whom it was removed was at the time seventy-nine years old when he fell on the ice and sustained this injury. He was kept in bed for some time and sand bags were used. He lived four years. There was a shortening of three and a half inches. It was remarkable how he got along with this condition.

Symphanometry.—Dr. P. H. EYKMAN of the Hague, Holland, demonstrated this apparatus. He said that in making a stereoscopic picture with *x*-rays he placed the body upon the plate and the *x*-ray tube at some distance, and so took one picture, for instance, to the left. The other was taken after changing the plate and moving the *x*-ray tube to the right. Since, for the mathematical reconstruction, the anticathodes must be replaced by the eyes, the distance between the anticathodes (base of exposure) must be equal to the distance of the optical centers of the two eyes (visual base) of the operator. In the mathematical reconstruction by a mirror stereoscope the virtual images must coincide with the original position of the negatives. The stereoimage appeared on the exact spot where the object lay, exactly the same size, and exactly the same shape, so that one might say that the stereoimage was congruent with the original object. It could be very easily proved that the operator had an exact reconstruction in using, instead of the ordinary opaque mirrors, transparent mirrors, and the *x*-ray image was to be seen exactly coinciding with the body itself. In the human body one would thus see the bones through the skin in their exact relative positions. This might serve as a guide to the surgeon during an operation, since he was able to apply his scalpel to the desired spot with mathematical accuracy. This method, *i.e.* the contemporaneous presence of the object itself, together with its Röntgen image, might be termed *symphany*. He then removed the object; then he only could see the Röntgen image as a nebula of a distinct form. With a white piece of paper he could touch every point in order to indicate exactly where it lay. They might hold a divided rule across this virtual stereoimage in any direction, and thus obtain the exact distance between two points. This method, which he called *symphanometry*, should prove of use for scientific measurement. They thus possessed in the stereogram not only a means of giving a general psychical impression, but also a register of the actual mathematical proportions. Perhaps this method could be of value in obstetrics for giving an exact notion of the shape of the pelvis. In certain cases it might be of advantage in making a record, when they combined *x*-ray with the ordinary photographic stereogram. To do this effectually the center of projection of the *x*-ray must coincide exactly with the optical center of the lens systems of the camera, and also the displacement must be the same in both cases. With the same camera they reduced the *x*-ray pictures to the same size as the photographic pictures, and they used a lens stereoscope with a transparent mirror at 45 degrees, so that they could view the two pictures at one time, and they would be seen to be quite congruent. It looked rather difficult for a physician to trouble himself so much with mathematics. Therefore he tried to make an instrument that did the work quite automatically. In the proceedings of the Royal Academy of Sciences of Amsterdam, March 17, 1909, one could find a full description of the theory. It was reprinted in the *Archives of the Röntgen Rays*, June, 1909.

Demonstration.—Under the aluminum sheet was a double plate holder, which only was to be turned for changing the plate. The plate was automatically numbered, the exposure base registered and marked with L or R for the left and the right plate respectively. The operator had only to adjust the instrument for his viewing base by turning a screw. The anticathode of the *x*-ray tube was adjusted by a special instrument in the dark room. The tube was easily connected with the instrument. By only turning the wheel to the right one brought the tube from the left into the right position. If he wanted also a photographic stereogram one replaced the tube by the camera and the exposures were made in the same way. Now the *x*-ray plates being developed, one changed the camera for the special mirror stereoscope called the symphanor. They were made in two shapes, one for the light coming from above, as in an operating room, the other for the light coming from the side. For reducing the Röntgen plates one also had an automatically working reducing instrument, so that the physician would have no trouble, as all the exact work was done mechanically.

MEDICAL SOCIETY OF THE COUNTY OF KINGS.

Stated Meeting Held March 19, 1912.

THE PRESIDENT, DR. ELIAS H. BARTLEY, IN THE CHAIR.

Postoperative Gastroenteric Paresis.—Dr. JAMES TAFT PILCHER of Brooklyn read this paper. He said that this condition was more frequent than was supposed, as in his hospital experience he had seen over sixty cases. Up to five years ago the mortality, which had been between 65 and 70 per cent., had diminished to below 5 per cent., and in the last ten cases there had been no fatalities. Gastroenteric paresis was observed during the course of the debilitating diseases, in the acute infectious diseases, as a result of brain and spinal injuries, and after operation. He believed that the dilatation of the stomach was due to a reflex inhibition of peristalsis and vomiting. The symptoms of the condition described were regurgitation of food, bile and fecal material, which simply welled up into the mouth; distention, which in none of his cases was limited to the stomach and which in some cases was absent because of the use of enemata; collapse, which was pathognomonic and usually developed within 24 hours; a feeling of distress, fulness, or pressure in the abdomen; intense thirst; and absolute obstipation. The conditions which simulated gastroenteric paresis were acute pancreatitis, acute intestinal obstruction, and acute perforative peritonitis, and these were easy of differentiation. The treatment was divided into prophylactic and active. By the former was meant thorough evacuation of the bowels before operation; the intravenous administration of 20 to 40 cubic centimeters of a hormone stimulating the peristaltic action of the intestine; minimum manipulation of the intraabdominal structures; a saline enema at 110° F.; a minimum use of ether by the open method; and the introduction of two ounces of olive oil into the mouth shortly after the patient's reflexes had become reestablished. The active treatment consisted of immediate lavage of the stomach, early, repeated, and prolonged; the use of stimulating enemata of turpentine, milk, or molasses in the place of eserin salicylate, which the speaker formerly used. He had since employed the hormone stimulating peristalsis. The speaker warned against the use of cathartics until after the stomach had been thoroughly evacuated. Installation of saline solution into the rectum by the drip method was used in some cases with good results. The treatment by posture was discouraged, as was operative interference.

Dr. ALGERNON T. BRISTOW in opening the discussion said that he had often met with the perplexing and disastrous condition described by the reader of the paper, and fully agreed in all that he had said. He emphasized the necessity of lavage. The stomach tube was to be introduced into the stomach as often as indicated, as it was the cornerstone of the treatment. Paralytic ileus was not always a preventable condition, as illustrated by the following case: Two years ago the speaker operated upon a man for the relief of an ileovesical fistula. The appendix was adherent to the bladder, and as the patient had a cardiac lesion one opening of the fistula was closed and no more openings were looked for. It was afterward found that another opening, which had not been discovered at the first operation, had not been repaired. After the operation the patient developed a severe attack of ileus with a distention so enormous that the sutures in the fascia gave way. But in spite of this the patient recovered, though he still had fecal evacuation through the urethra. Before his second operation elaborate steps for the prevention of a postoperative ileus were taken. He received castor oil and salol for one week previous to the operation and immediately after the operation, before the development of ileus, the administration of eserin salicylate every four hours was begun. The ileus that again developed was not as severe as after the first operation, but it was bad enough. The patient's stomach became dilated and there was regurgitant vomiting first of bile and later of fecal matter. The eserin was

discontinued on the third day. On the fourth day Dr J. T. Pilcher injected peristaltic hormone intravenously after which the patient vomited but once. Within four hours after its administration the patient began to pass gas per rectum and soon afterward he had a stool. Since then he had had regular bowel movements daily.

Dr. Joseph Merzbach considered the subject from the medical viewpoint and divided these cases into three groups: First, the cases of chronic dilatation which were rare and were found in beer drinkers. Second, the subacute types in which the dilatation was due to an obstruction of the pylorus. Of this type the speaker mentioned two cases: one of gastric ulcer with regurgitant vomiting and cure after operation, and the other a case of pyloric adhesions. In this case lavage was used and no food per os was permitted. The dilatation of the stomach in the infectious diseases belonged to the third group. The speaker had seen four cases following pneumonia occurring just before the crisis. The diagnostic signs were either a globular prominence in the epigastrium, which Dr Pilcher said was very rare, or a disturbance of the typical pneumonia temperature-pulse ratio. This disturbance was always due either to a myocarditis or to a mechanical interference with the heart. The speaker finally emphasized the importance of using the stomach tube in dilatation no matter how ill the patient might be, because without this treatment the patient would die.

Dr. William J. Cruikshank recollected his first case of appendicitis which was operated upon by McBurney and which developed ileus. McBurney at that time remarked that all these cases were fatal. The speaker believed that many of the vasomotor paralyses complicating pneumonia were really fatal cases of intestinal paresis.

Dr. John C. MacEvitt remarked that the symptoms of gastroenteric paresis were plain. The vomiting was not continuous, but ceased for hours at a time and then was propulsive in character. The speaker insisted on the repetition of gastric lavage until the fluid returned clear and it was remarkable how great a quantity had at times to be used. The pain was not continuous and pressure could be made on the abdomen without evoking tenderness as in peritonitis. The latter symptom he regarded as of great value.

Dr. James T. Pilcher in closing remarked that the case described by Dr. Bristow did not come under the heading of the paper, but was really a case of retrograde peristalsis due to a misapplication of the normal stimulus to the bowel.

On the Problem of the Prevention of Insanity.—Dr. August Hoch of Ward's Island read a paper with the above title. He commented on the present status of prevention in general medicine, dwelling at length on its relation to the prevention of insanity. He stated that there existed a belief that insanity was increasing, but personally he did not think this was so as no proof of progressive mental degeneration had been shown. He said that the hospitals for the insane were overcrowded and that the increase in demands for admission to these hospitals was greater than a proportionate increase in population. He believed that this state of affairs was due to the earlier recognition of the disease, to the better facilities for treatment in the hospitals, and to other factors too numerous to mention. Even if there was an increase in mental degeneracy and insanity the outlook was not gloomy and there was no reason why insanity should not enter the field of preventive medicine. The speaker classified cases of insanity under three heads: First, those suffering from organic mental diseases, as general paresis, brain syphilis, arteriosclerotic dementia, alcoholism, Korsakoff's psychosis, delirium tremens, and the toxic insanities. These cases had a chronic and progressive course with defective memory and organic cerebral changes. To the second group belonged mania, melancholia, and the manic depressive type of insanities, and the speaker defined these as deviations of the emotions. In the third group he included hysteria, paranoia, and dementia præcox, terming them disorders of adjustment. In order that he could outline the means of prevention of these diseases the speaker first discussed the causes. The latter were exogenous as in the first group of the above, and endogenous as in the other two groups. In every case of general paresis syphilis was the causative factor, but there were contributory factors. Twelve per cent. of all admissions to the New York hospitals for the insane were general paretics and of the males 20 per cent. suffered from this disease. The mortality in New York for 1910 from this cause was one-half as great as that from typhoid fever. Syphilis was also the etiological factor in many cases of meningitis and endarteritis, as well as in many congenital brain affections. Many organic brain defects could be prevented by instituting a general campaign against syphilis. It was more difficult to estimate the number of cases of insanity traceable to alcohol. Experiments had tended to prove that alcohol led to mental degeneration in the offspring. A conservative estimate showed that about 12 per cent. of all admissions were due to alcohol primarily. A campaign against alcohol addiction was also necessary. At least one-quarter of all cases admitted to the hospitals for the insane for organic diseases were preventable by simple, clear-cut means. The endogenous causes were more difficult to control as it was of greatest importance to know the personal life of the individual. Usually these patients were less resistant mentally, not being able to withstand stress and strain, and they always showed danger signs. The prevention of hereditary weak-mindedness by controlling marriage or by vasectomy was of questionable value, as the true indications for these procedures were not clear. The speaker emphasized the importance of close observation of the individual during childhood, especially regarding the sexuality. Tendencies to day-dreaming, depression, and brooding were to be guarded against. Many cases of insanity could have been avoided by gaining the child's confidence or by having more attention paid to slight mental abnormalities. Comment was made on the lack of alertness in detecting early signs of mental breakdown. Finally, the speaker insisted that there was a field for preventive psychiatry by means of treatment. Medical schools gave instruction in the recognition of well developed cases of insanity, but more attention ought to be paid in teaching the early signs of mental impairment.

Dr. W. L. Russel of the Bloomingdale Asylum said that he was gratified in that he had observed the closer relation of general medicine to practical psychiatry. The general practitioner dealt with more mental cases than he realized. The speaker based this statement on the fact that most of the cases admitted to the hospital gave a previous history of about eleven months' duration and many of the discharged patients received further treatment. Fully 25 per cent. of court and jail cases included individuals who were more or less insane. All these cases had been seen originally by the general practitioner. Considering the fact that there were only fifteen public and twenty private asylums in New York State with facilities for caring for 30,000 patients, he thought it was the duty of the medical profession to urge the provision of more adequate facilities for the care of these unfortunates. Stress was laid on the importance of arousing public interest in the prevention of insanity.

Dr. Salmon referred to the work of the National Society of Mental Hygiene. Its main object was the improvement of the condition of the insane and for this object greater uniformity in the commitment and treatment of these cases in the various States was necessary.

Pathological Society of Philadelphia.

At a stated meeting held March 14 Dr. Kenneth M. Lynch exhibited a specimen of "Congenital Constriction of the Bowel." The patient was an infant, six weeks old, born by cesarean section. During life it exhibited great distention of the abdomen, with vomiting and evidences of inanition. On post-mortem examination the stomach, as well as the first part of the small intestine, was found greatly distended, while the jejunum was the seat of a valve-like fold, with a small opening, preventing the onward passage of the intestinal contents. Dr. Lynch presented also "Specimens from a Case of Congenital Syphilis Dying Shortly After Administration of Salvarsan." The patient was a girl, nine years old, with evident symptoms of congenital syphilis and who following a second intravenous injection of salvarsan developed vomiting, diarrhea, and collapse, followed by death. On post-mortem examination degenerative changes were found in the kidneys, the liver, and the heart. Dr. Daniel J. McCarthy presented a communication describing "Sections of Brain-tissue Showing the Reaction of the Cerebral Tissues in Syphilitic Perivasculitis to Salvarsan." The patient was a man who had presented delusions of persecution followed by progressive dementia, together with a positive Wassermann reaction. Injection of salvarsan was followed by coma and death. On post-mortem examination evidences of syphilis were found in brain and cord, but no changes that could be referred to the effects of the therapeutic agent. Drs. B. A. Thomas and R. H. Ivy exhibited a patient presenting "Hyphomycosis." The patient was a young colored man employed as an embalmer who presented a circumscribed lesion rather larger than a silver dollar on the dorsal aspect of the left wrist. The base and margins were reddened, while the affected area was cov-

ered by a crust honeycombed with innumerable small openings from which pus could be readily expressed. Examination of smears and cultures from the discharge disclosed the presence of a fungus of the hyphomyces group, but whose precise identity had not been established. Noteworthy improvement followed upon applications of mercuric chloride and carbolic acid. Drs. JOHN A. KOLMER and JAY F. SCHAMBERG presented a communication, "A Study of Experimental Histological Changes Following the Administration of Sarvarsan." The object of the investigation was to determine whether the remedy could be administered safely and effectively by the mouth. Accordingly, doses exceeding physiological limits were given to cats and dogs and rabbits in the form of capsule, pill, and with food, without causing more disagreeable symptoms than vomiting and diarrhea. Within 24 hours and up to 72 hours arsenic could be found in the urine, the bile, the bowel, and the stomach, while the bacterial flora of the intestine exhibited a quantitative diminution. No noteworthy histological alterations were discovered in any of the viscera examined. The remedy was administered also to several patients suffering from syphilis and it exhibited therapeutic activity, but less marked than when administered into a vein or into a muscle. Dr. JOHN H. MUSSER, JR., presented a communication entitled "Experimental Study of the Changes in the Blood Following Splenectomy." Observations in cases of splenectomy in human beings, a case of which had been under Dr. Musser's care, showed that removal of the spleen is followed by a reduction in hemoglobin and in the number of red corpuscles and an increase in the number of leucocytes, lasting for a considerable period of time. Similar changes were observed in animals from whom the spleen was removed experimentally. Drs. R. M. PEARCE, J. H. AUSTIN, and E. B. KRUMBHAAR presented a communication entitled "Experimental Study of the Influences of Splenectomy on the Production of Hemolytic Jaundice." Dr. ALFRED STENGEL presented a communication entitled "Pneumococcus Infection with Hemolytic Jaundice." He reported the case of a man, 54 years old, who complained of pain at the base of each chest, with elevation of temperature and leucocytosis. Physical signs of pneumonia could not be detected. In the course of a few days a striking orange-tinted jaundice developed, while the leucocyte count rose progressively and the patient's condition was obviously becoming increasingly grave. Pneumococcemia was suspected, but the patient died before the results of culture, showing the presence of pneumococci in the blood, could be reported. At autopsy pneumonic consolidation of the upper lobe of the left lung was found, with degenerative changes in the liver. Dr. A. P. HITCHENS presented a communication entitled "Contribution to the Study of Passive Immunity to Tetanus," as a result of which he was able to show that the immunity induced in horses by the administration of antitoxin was temporary, lasting about one month in experimenal animals.

Books Received.

The MEDICAL RECORD *is pleased to receive all new publications which may be sent to it, and an acknowledgment will promptly be made of their receipt under this heading, but it must be with the distinct understanding that it is under no obligation to notice or review any publication received by it which in the judgment of its editor will not be of interest to its readers.*

PRACTICAL GYNECOLOGY. By E. E. MONTGOMERY, M.D., LL.D. 4th Edition. 857 pages; with 589 illustrations; cloth; price $6.00 net. P. Blakiston's Son & Company, Publishers, Philadelphia.

THE SURGICAL CLINICS OF JOHN B. MURPHY, M.D., AT MERCY HOSPITAL, CHICAGO. Vol. I, No. 1; 133 pages; illustrated; price per year; paper, $8.00. Cloth, $12.00. W. B. Saunders Company, Publishers, Philadelphia.

A COMPEND OF GENITO-URINARY DISEASES AND SYPHILIS. By CHARLES S. HIRSCH, M.D. 359 pages; illustrated; price, cloth, $1.25 net. P. Blakiston's Son & Co., Publishers, Philadelphia.

ARZNEI UND DIÄT-VERORDNUNGEN FÜR DIE GYNÄKOLOGISCHE PRAXIS. By Prof. Dr. PAUL STRASSMAN. 192 pages; paper; price 1.60 M. August Hirschwald, Publisher, Berlin.

BEITERÄGE ZUR EXPERIMENTELLEN THERAPIE. By Prof. Dr. E. v. Behring. 114 pages; paper; price 6 M. August Hirschwald, Publisher, Berlin.

MODERN THEORIES OF DIET. By Alexander Bryce, M.D., D.P.H. 368 pages; cloth. Longmans, Green & Co., Publishers, New York.

Medicolegal Notes.

Malpractice—Responsibility for Operation Conducted by Another.—There is no rule of responsibility which requires of a physician or surgeon infallibility in the diagnosis or treatment of diseases. The plaintiff in an action for malpractice had for some years been treated by the defendant and other medical men for tic douloureux, for which medicaments had been of no avail. The defendant, who kept a hospital, advised an operation, and after consulting with the plaintiff procured his brother, who made a specialty of surgical cases, to perform the operation. It was not successful in relieving the plaintiff's sufferings, and it left him with some disfigurement, and without the protection afforded to the brain by the hard plate of his skull over an area of 2½ by 1½ inches. The plaintiff recovered a verdict and judgment for a substantial sum and the defendant appealed.

In one aspect of the case the plaintiff claimed that the defendant caused a dangerous operation to be performed upon him after assuring him that the operation to be performed would be a mere trifle, as operations go, and would involve no serious consequences. If that contention were true defendant's conduct would be indefensible. But the Alabama Supreme Court held that, on the evidence, the verdict, if based on that aspect of the case, ought not to be allowed to stand. The defendant was a reputable physician, having the plaintiff's confidence, and had treated the plaintiff at intervals since childhood and during many months for the specific disease. The operation was performed in the presence of three other physicians, nurses and three brothers of the plaintiff. It was dangerous, difficult, and of doubtful result at the best. The defendant and two of the other physicians swore that the plaintiff was specifically informed of the nature of the operation. Nearly a year elapsed after the operation before the plaintiff intimated that he had a grievance, and within that period he had returned to the defendant for treatment and consulted with him about having the operation repeated. It was also complained that the defendant had unskilfully or negligently diagnosed or treated the plaintiff's case. There was no evidence of error in diagnosis. As for any unskillfulness or negligence in the operation, assuming that the jury were authorized to find that there was such, the operation was not performed by the defendant, but by another surgeon under the circumstances above stated. The defendant took part to the extent only of administering the anesthetic and advising that the effort to complete the operation be abandoned on account of the patient's ebbing vitality. There was no suggestion that in these things he showed any lack of skill or committed any error. Nor was there any suggestion in pleading or in proof that the defendant negligently advised the employment of an unskillful or incompetent surgeon to perform the operation. Under these circumstances the defendant was not responsible for any default on the part of the operating surgeon, who was practising his profession as an independent agent. It was also argued that the defendant contributed to the result of the operating surgeon's alleged negligence by furnishing an inadequately equipped place in which to perform the operation. That, however, it was held, left the question at issue to depend upon the defendant's responsibility for the operating surgeon, for if, it was said, the condition of the hospital and its equipment was such as, in itself, to impart an element of negligence or unskillfulness into an operation performed there, the responsibility for that element of the operation rested upon the surgeon, who determined upon and directed the operation. Moreover, the medical men, including one of the plaintiff's witnesses, gave their approval to the hospital. The judgment for the plaintiff was therefore reversed and the case remanded.

Various instructions to the jury on the liability of physicians were considered and approved. An instruction that no matter how skillful a physician may be he is responsible for his negligence, if any, was held not objectionable as holding a physician responsible for his negligence without limiting the responsibility to the proximate results of his negligence. Although the plaintiff had a temperamental or physical weakness which could not be foreseen, and which contributed to the failure of the operation, the defendant would nevertheless be liable, if he contributed to the plaintiff's injury by a failure to exercise due care and skill or by performing upon the plaintiff a serious operation without his consent, express or implied. Although there might arise emergencies in which a surgeon might operate upon his patient without his knowledge and consent, this was not a case of that character.—Robinson *v.* Crotwell, Alabama Supreme Court, 57 So. 23.

Finger Print Impressions as Evidence.—On a trial for murder objection was taken, in the Illinois Supreme Court, to the admission in evidence of enlarged photographs of impressions of the accused's finger marks upon a railing, on the ground that this class of testimony is not admissible under the common law rules of evidence, and as there is no statute in the State of Illinois authorizing it the court should have refused to permit its introduction. The court said that it had found no statutes or decisions touching the point in this country. This class of evidence has been admitted in Great Britain, and the standard authorities on scientific subjects discuss the use of finger prints as a system of identification, concluding that experience has shown it to be reliable. These authorities state that this system of identification is of very ancient origin, having been used in Egypt, when the impression of the monarch's thumb was used as his sign manual; that it has been used in the courts of India for many years and more recently in the courts of several European countries; that in recent years its use has become very general by the police departments of the large cities of this country and Europe; and that the great success of the system in England, where it has been used since 1891, in thousands of cases without error, caused the sending of an investigating commission from the United States, on whose favorable report a bureau was established by the United States government in the war and other departments. From the evidence of expert witnesses who testified in the case and from the writings referred to, the court held that there is a scientific basis for the system of finger print identification, and that the courts are justified in admitting this class of evidence; that this method of identification is in such general and common use that the courts cannot refuse to take judicial cognizance of it. The evidence may or may not be of independent strength, but it is admissible, the same as other proof, as tending to make out a case. It was also held that expert evidence is admissible on the subject, the classification of finger print impressions and their method of identification being a science requiring study. The evidence on the subject did not come within the common experience of all men of common education in the ordinary walks of life, and therefore the court and jury were properly aided by witnesses of peculiar and special experience on the subject.—People *v.* Jennings, Illinois Supreme Court, 96 N. E. 1077.

Testamentary Capacity—Effect of Disease.—In an action to set aside a will the theory of the contestant was that the disease from which the testator suffered, cancer of the tongue, broke him down so physically and mentally that he was incapable of making a will. Some of the witnesses testified that they had seen the testator, who was a man of 76 years of age at the time of execution of the will, cry, and it was urged that this was a sign of mental unsoundness in a man. It was held that, while that was true when it was the result of little or no provocation or cause, it would be unreasonable to say that, because the deceased, who sometimes suffered intense pain, gave voice to his sufferings by crying out and shedding tears that he was mentally unsound.—Beemer *v.* Beemer, Illinois Supreme Court, 96 N. E. 1058.

Dentist Not a Surgeon Within Statute on Privileged Communications.—In an action by a duly licensed dentist to recover the agreed price of professional services rendered to the defendant's testator it was urged by the defendants that the plaintiff's testimony relating to the work which he did for the testator was objectionable under the provision of Section 834 of the New York Code of Civil Procedure that "a person duly authorized to practise physic or surgery or a professional or registered nurse, shall not be allowed to disclose any information which he acquired in attending a patient, in a professional capacity, and which was necessary to enable him to act in that capacity," etc. Assuming the section to be applicable to a dentist, the court did not think it clear that the testimony of the plaintiff as to the number of visits and the work which he did, not in the presence of the deceased, would be within its prohibition. It thought, however, that it was clear that the Legislature did not intend to include a dentist within the provisions of that section of the code. Strictly speaking, a dentist might be included within the description relating to those who practise "surgery," but as the term "surgery" is employed in the statute it does not include one engaged in the practice of dentistry.

At common law, communications between physician and patient were not legally privileged. The legal privilege seems first to have been recognized in New York in 1828. To the extent, therefore, to which the privilege can now be said to exist, it must find its support in some statutory enactment. In early days in England the province of the dentist was not recognized, except as it fell within the scope of the "barber surgeon," whose multitudinous duties often included those, not only of the barber and surgeon, but the physician and dentist as well. Within quite recent times it was customary for barbers and blacksmiths to extract teeth. Formerly the work of filling and plating teeth was frequently performed by the jeweler. A process of integration and differentiation has taken place, and the separate and distinct profession of dentistry has come into existence. That this specialization has resulted beneficially to the community, and that dentistry has now become a highly developed science, requiring of its practitioners advanced knowledge and skill is doubtless true; but this fact does not militate against the construction of Section 834 of the New York Code of Civil Procedure excluding a dentist from the operation of its provisions. There is clear evidence in the statutes of the State of a legislative intent to regard the two professions of medicine and dentistry as separate and distinct. Thus the practice of medicine is governed by article 8 of chapter 49 of the Laws of 1909 (Consol. Laws, c. 45), while the practice of dentistry is regulated by a different law, and applicants for admission to practise dentistry are admitted by different boards of examiners and registry (article 9, c. 49, of the Laws of 1909). There is also another statute of the State which, while not strictly *in pari materia*, deals with a cognate subject, and should therefore be considered in interpreting the statute under consideration. It is not without significance that the statute, which provides for exemption from jury duty mentions not only a physician and surgeon but provides that the exemption shall apply to "a practicing physician, surgeon, or surgeon dentist." Section 635 of the Judiciary Law (Consol. Laws, c. 30).

The question has also been considered by the Michigan Supreme Court, which, construing a similar statute, said that "the purpose of the act is to be considered in determining whether the dentist was intended to be included within its terms. Certainly the terms 'dentist' and 'surgeon' are not interchangeable, and if a dentist is to be held a surgeon, within the meaning of this act, it must be because his business as a dentist is a branch of surgery. It is apparent that the act relates to general practitioners and to those whose business as a whole comes within the definitions of 'physician' or 'surgeon.' A dentist is one whose profession is to clean and extract teeth, repair them when diseased, and replace them, when necessary, by artificial ones."—People *v.* De France, 104 Mich. 563.

While considering the definition of a dentist here given rather restricted, the New York court approved of this interpretation of the statute and held that the plaintiff was not precluded from testifying within the provisions of Section 834 of the Code.—Howe *v.* Regensburg, 132 N. Y. Supp. 837.

Scope of Privileged Communications.—The provision of the Indiana statute providing that physicians shall not be competent witnesses as to matters communicated to them by patients in the course of their professional business is broadly construed by the Indiana courts to include not only communication and advice but all information acquired by the physician while treating or attending the patient in his professional capacity. And this has been applied to include as privileged a patient's communication of her financial condition made to her physician, who, in the course of a consultation, was urging her to take a vacation.—Hays *v.* Hays, Indiana Appellate Court, 97 N. E. 108.

Municipality's Power to Contract for Medical Services.—In an action by a physician for the balance of salary alleged to be due to him under his appointment as city physician it was held that as the city charter did not provide for any such office as city physician it was beyond the power of the common council to create an office which the statute made no provision for. Nor had the city, under its general power, "to enter into contracts for services or supplies and order payment of the same, and to provide generally for the welfare of the city" power to enter into a contract with the plaintiff to give medical treatment to the members of the various city departments, including fire and police, and to attend upon the indigent poor of the city. As the city had no power to employ the plaintiff for a definite term as it attempted to do, it could therefore terminate his employment at a fixed compensation at its pleasure.—Jacobs *v.* City of Elmira, New York Appellate Division, 132 N. Y. Supp. 54.

Expert Evidence in Murder Case.—A doctor who was shown to have the necessary qualification was held in a murder case in which the defense was self-defense to be properly allowed to testify, over objections, as to what were the indications as to the weapon being close to the body when the shot was fired.—State *v.* Johns, Iowa Supreme Court, 132 N. W. 833.

Medical Items.

Renal Therapeutics in Some Obstetrical Cases.—V. Cova has experimented on six cases of nephritis at the Obstetrical Institute of Milan by using the serum drawn from the renal vein of the goat and injecting it into the patients' veins. He finds that the remedy is harmless and produces beneficial effects on the kidney disease. The cases included two of albuminuria of pregnancy; two of chronic nephritis; one of chronic nephritis and uræmia, and one of poisoning with corrosive sublimate, affecting the kidney. The author found that there was an increased diuresis, a lessened albuminuria, and an increased permeability of the kidneys for chlorides. The clinical results were improvement in the general condition, in the feeling of well-being, and in the rhythm and fulness of the pulse, diminution in the headache, dyspnea, and arterial tension, and an improved gastric condition. If the remedy is stopped the improvement of the symptoms passes away. The author advocates further tests of the therapeutic value of goat serum in the renal diseases of pregnancy.—*Annali di Ostetricia e Ginecologia.*

Prevention of Deafness Among School Children.—P. Jacques states that the deaf child gains little in school, because he hears so little of what is said. He learns only by the eyes. In the great majority of cases the alterations which cause deafness are slow and progressive and are not noticed by the parents. It is only by careful and systematic tests of the hearing of school children that we are able to note the beginning of the deafness, and by treatment to prevent its increase. The damage to the ear occurs generally during the first few years of life. Frequent inflammatory disturbances of the nasopharynx have a bad effect on the hearing and result later in sclerosis and loss of hearing. It is in the primary school that these examinations should be made and treatment of the adenoids and tonsils should be undertaken as a preventive. Most cases of deafness begin early in life from nasopharyngeal inflammations.—*Journal de Médecine de Paris.*

Myxedematous Coma.—E. Hertoghe states that in myxedema there occurs in the brain and in the rest of the nervous system an infiltration with myxedematous tissue, with resulting mental torpor, headache, vertigo, slowness of speech, and tinnitus. In some cases this condition goes on to a true coma of dysthyroidean origin, which condition may terminate fatally. It is generally mistaken for nephritic or diabetic coma, particularly when a small amount of sugar or albumin is found in the urine. When there is a coma that is referable to neither nephritis, diabetes, traumatism, nor hemorrhage, one should always think of myxedema and dysthyroidea. The treatment by means of thyroidin is successful. The substance may be injected, or introduced by way of the stomach or rectum. In cases of extreme urgency a lumbar puncture may be made for the purpose of introducing the substance in solution.—*Société Medico-Chirurgicale d'Anvers.*

Epidemic of Icterus in Soriano and Cimino and Its Relation to Pregnancy.—E. Cova describes an epidemic of 145 cases of icterus in a town with 6000 inhabitants at a high altitude. This epidemic began with a puerperal patient who soon died with symptoms of acute yellow atrophy of the liver. From this case the epidemic spread until many of the inhabitants were attacked. In general the cases were benign and without fever. There were malaise, loss of appetite, and weakness, followed by a moderate degree of icterus. The disease lasted about three weeks. Most of the cases that were fatal were among pregnant women, of whom 23 were attacked. In general there were no bile pigment in the urine and no albumin. The liver was enlarged. Ten pregnant patients died. Abortion resulted in only 1 case. There were 5 primiparæ, of whom 4 died; of 13 multiparæ only 3 died; thus the disease was more fatal among primiparæ. During pregnancy there are in the liver changes which are aggravated by this condition. Such epidemics are not rare, and are shown by published accounts to be especially fatal among pregnant women. The other fatal cases are generally those of individuals who have already poisoned their livers with alcohol or syphilis. This epidemic was probably of bacterial origin, but the germs could not be isolated. The evidence of contagion from one case to another is conclusive.—*Folia Gynecologica.*

Treatment of Graves' Disease with Pituitary Extract.—A. Salmon finds that in cases of exophthalmic goiter the use of pituitary extract soon relieves the sleeplessness, tremor, disturbances of digestion, painful sensations of heat, and tachycardia. Arterial tension increases, exophthalmos decreases, and the goiter becomes smaller or remains stationary. When the extract is stopped the symptoms again increase. The author reports the results in two cases of exophthalmic goiter treated in this way. It has been found that hypophyseal extract causes vasoconstriction in the thyroid vessels and hypertrophy of the thyroid. The vesicles become full of colloid substance such as is seen in hypofunction of the gland. There is an intimate relation between the action of the thyroid and hypophysis; when one of these glands is disturbed the other is also affected. None of the glands of internal secretion is seldom affected alone, the others also suffering from the same cause. The ovaries, thyroid, and suprarenals are all similarly affected. There is a multiglandular syndrome. Lowered arterial tension, tachycardia, insomnia, asthenia, hyperidrosis, and sensation of heat all denote insufficiency of the hypophysis, and all are seen in Graves' disease. Hence there is probably a lesion of the hypophysis in this disease. All these symptoms are relieved by pituitary extract. The relief of insomnia is not difficult to understand if one remembers that the hypophysis exerts a marked influence on the nutrition of the nervous tissues.—*Il Policlinico.*

Vegetating Cysts of the Mammary Gland.—D. Angier and M. Dekester describe vegetating cysts of the mammary glands as developing from dilatations of the glandular acini or ducts, and occurring in the neighborhood of the nipple, sometimes adherent to the skin. They may degenerate and involve the neighboring glands. In general they are benign in evolution. They are of the histological type of cylindrical-celled papillary epithelioma, and the analogy with vegetating epithelioma of the ovary is complete. The internal walls are covered with cauliflower-like vegetations developed from the lining epithelium of the cyst. The contents are a straw-colored fluid which is sometimes tinged with blood. The cysts should be without delay removed.—*Journal des Sciences Médicales de Lille.*

The Wassermann Reaction in Fetal Monstrosities.—Montanelli performed the Wassermann test in nine of these cases, testing the blood serum of both parents and of the monster taken from the cord, and in one case the amniotic fluid. He obtained a positive reaction in one instance only, in a case in which the mother had an arterial hemiplegia. There can be no doubt that the condition of the parents has an important influence on the production of these monsters. Intoxications of various kinds, syphilis, and tuberculosis have their effect not by direct transmission of the microorganism, but by the general effect on the tissues and the constitution of the fetus. The author believes that the Wassermann reaction is of positive value in the diagnosis of the cause of fetal monstrosities.—*Rendiconti delle Societa Toscana di Ostetricia e Ginecologia.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended March 22, 1912:

Places.	Date.	Cases.	Deaths.
CHOLERA			
India: Bassein	Jan. 21–27	15	15
Calcutta	Jan. 21–27	.	49
Madras	Feb. 4–10	26	18
Total Madras Presidency, Jan. 1–31. Cases, 13,411, deaths, 8,509.			
Negapatam	Jan. 14–27	..	42
Siam: Bangkok	Dec. 31–Jan. 27	..	196
Turkey in Asia: Aleppo	Feb. 18–24	4	3
Provinces, Jan. 22–Feb. 5. Cases, 11; deaths, 27.			
PLAGUE.			
China: Hongkong	Jan. 26–Feb. 3	9	8
Hawaii: Honakaa	Mar. 18	1	1

PHYSICAL EXAMINATION A REQUIREMENT FOR A CORRECT DIAGNOSIS AND THE HONEST TREATMENT OF THE SICK.

WITH BRIEF REFERENCES TO CASES ILLUSTRATING INEXCUSABLE ERRORS.*

BY ARTHUR M. JACOBUS, M.D.,

NEW YORK.

AT the outset it must be stated that this is not a paper on physical diagnosis, nor one on mistakes due to poor judgment, or illogical analysis of the presenting symptoms, but that it is a plea for the exercise of greater care and better diagnostic methods, and more especially a protest against the seemingly frequent failure to make a physical examination of patients by certain physicians, and which, it will be admitted, should be made in all cases or conditions, when and where possible, in order that a tentative diagnosis at least may be made before a physician shall assume charge of or treat a sick or injured person.

This charge of neglect has been questioned by several colleagues, in conversation regarding the subject under consideration, on the ground that, while it may apply to older graduates in medicine, it does not apply to, or is of very infrequent occurrence, in the practice of the younger graduates.

My professional experience dates back thirty-six years, every year of which has been in affiliation with either a hospital, or a dispensary, or a clinic, in an undergraduate or postgraduate institution, and it has seemed to me that there have come to my notice as many, if not more, errors in the past decade from failure to make a physical examination than in the earlier years of my practice.

It may seem a slander on the profession to-day to make such an assertion, but unfortunately such has been my frequent experience, as it must also have been that of many physicians connected with public clinics where the "flotsam and jetsam" of the sick poor drift.

Errors of omission are no doubt largely due to hasty, thoughtless, or unsystematic methods of examination, perhaps, at times, because of the rush of practice, but judging by the frequent statement of patients, there has often been no examination whatever, not even a perfunctory one.

To treat a patient under such conditions is certainly dishonest, if not really malpractice.

In order that you may not consider the latter statement unwarranted let me quote a decision of the highest court of this state, as to what malpractice is.

*Read at a meeting of the Northwestern Medical and Surgical Society of New York City, February 21, 1912.

This opinion was very kindly furnished to me by the counsel of the Medical Society of the County of New York, and is as follows:

"The principle of the law concerning which you inquired was stated as follows by Mr. Justice Vann, in the case of Pike vs. Honsinger, in 1898, and reported in 155 N. Y., page 201:

"'The law relating to malpractice is simple and well settled, although not always easy of application. A physician and surgeon, by taking charge of a case, impliedly represents that he possesses, and the law places upon him the duty of possessing, that reasonable degree of learning and skill that is ordinarily possessed by physicians and surgeons in the locality where he practises and which is ordinarily regarded by those conversant with the employment as necessary to qualify him to engage in the business of practising medicine and surgery.

"'Upon consenting to treat a patient, it becomes his duty to use reasonable care and diligence in the exercise of his skill and the application of his learning to accomplish the purpose for which he was employed. He is under the further obligation to use his best judgment in exercising his skill and applying his knowledge. The law holds him liable for any injury to his patient resulting from want of the requisite knowledge and skill, or the omission to recognize reasonable care, or the failure to use his best judgment.

"'The rule in relation to learning and skill does not require the surgeon to possess that extraordinary learning and skill which belong only to a few men of rare endowments, but such as is possessed by the average member of the medical profession in good standing. Still he is bound to keep abreast of the times, and a departure from approved methods in general use, if it injures the patient, will render him liable, however good his intentions may have been.

"'The rule of reasonable care and diligence does not require the exercise of the highest possible degree of care, and to render a physician and surgeon liable, it is not enough that there has been a less degree of care than some other medical man might have shown, or less than he himself might have bestowed, but there must be a want of ordinary and reasonable care, leading to a bad result. This includes not only the diagnosis and treatment, but also the giving of proper instructions to his patient in relation to conduct, exercise, and the use of an injured limb.

"'The rule requiring him to use his best judgment does not hold him liable for a mere error of judgment, provided he does what he thinks is best after careful examination. His implied engagement with his patient does not guarantee a good result, but he promises by implication to use the skill and learning of the average physician, to ex-

exercise reasonable care and to exert his best judgment in the effort to bring about a good result.

"ALMUTH C. VANDIVER,
"*Counsellor-at-law.*"

Three essentials are necessary for the making of a diagnosis:

1. A good working knowledge of the anatomy and of the physiology of the human body and its organs.

2. A careful physical examination of the sick or injured person, partly or entirely nude, a "sine qua non," as may be necessary, and also of such of his body fluids, secretions, and excretions as may be indicated and obtainable.

3. The use of common sense and an observing mind in order to form a proper conclusion and a logical diagnosis from the objective and subjective symptoms present.

These simple elementary propositions are self-evident and need no advocacy to any honest and intelligent practitioner, neither do they preclude the knowledge of other desirable aids, such as a more or less familiarity with chemistry, pathology, bacteriology, and modern clinical laboratory methods, which frequently are necessary in the making of an accurate and complete differential diagnosis in the many complex morbid conditions coming under observation and requiring wide knowledge, skilful technique, and a large clinical experience for their solution. Yet "with all our varied instruments of precision, useful as they are, nothing can replace the watchful eye, the alert ear, the tactful finger, and the logical mind which correlates the facts obtained through all these avenues of information and so reaches an exact diagnosis."*

"No small part of the greater success which attends modern treatment when compared with the treatment of former days is to be ascribed to the vast improvements made in the art of recognizing disease and of distinguishing one disease from another."†

A correct diagnosis, then, is the first step in treatment, and more, it is hardly an exaggeration to say that an exact diagnosis and a correct appreciation of the whole morbid condition present in the patient is half the treatment.

A diagnosis is based partly on the history of the patient, partly on his own account of his symptoms, and partly on the physician's or surgeon's physical examination of the patient.

While the relative value of these three sources of information varies in different cases, certainly a physical examination of the patient, stripped as indicated, is absolutely necessary, and should be made in all instances where any injury or organic, or even a functional disease, is suspected.

From conversations held with many patients in private, and especially in clinic practice, covering years, I feel certain that careless methods and neglect to make a proper physical examination has resulted in many instances, in a failure to recognize even a clearly defined disease from which the patient suffered, and not infrequently in unnecessary, and in unsuccessful, if not in harmful, treatment also. Further, I believe that such carelessness and neglect has caused many patients to seek relief through the dispensaries and hospitals where, it was presumed, intelligent and careful physicians might be found and successful treatment obtained. Physicians connected with such institutions will, no doubt, bear me out as to the truth of the foregoing statement. I believe also that that is the chief reason why so many well-to-do patients flock to public clinics and hospitals, and, worse yet, to quacks of all kinds and sects who promise so much and delude so easily and so frequently.

In answer to the question as to whether a given patient was not able to employ a private physician and why he or she came to a public clinic, the answer has frequently been that they had spent their entire savings with one physician or another without a determination of their disease, or material benefit, and not knowing where else to go for relief had felt compelled to go to a public dispensary.

As further proof of this, who has not at some time been consulted by a patient, in a clinic, for the mere purpose of obtaining a thorough examination and diagnosis, followed by a request for a certificate as to the nature of their disease. In fact, not only do patients voluntarily seek such examination for the purpose stated, but not infrequently the family physician imposes on the clinic physician, surgeon, or specialist, by secretly encouraging his patient, under the guise of poverty, perhaps, to seek such information in that underhanded way, and thus obtain a free consultation for his own and his patient's benefit. Such has been the experience of many clinic physicians, I am sure, as it has been that of mine.

The clinic physician may have his faults and be too ready at times to treat gratuitously the undeserving for the sake of experience and the reputation of his clinic, but others have their faults, also, and in some instances, apparently for purely mercenary reasons, at the same time doing an injustice to some of their professional colleagues who should have been openly called in in consultation.

To refer again to the subject of the paper, the necessity of making a thorough physical examination of the patient and of his body fluids, as indicated (in order to make a diagnosis) before commencing treatment, it is admitted that mistakes occur, even after a careful examination.

"Nor is this surprising when one remembers the extent of modern medicine and the impossibility of any one man mastering it as a whole and making himself practically familiar with each of its individual parts in detail; the extreme complexity of many of the problems with which the physician has to deal; the elaborate and highly technical nature of some of the chemical, instrumental, and other methods of clinical examination and research which we employ; the insufficient data on which we have to found our opinions; the great difficulty we often have in eliciting and observing facts; the circumstances that in some cases we have to rely upon the statements and observations of the patient or his friends for some of the data on which our opinions have to be based and that those statements and observations are often inaccurate and sometimes positively misleading; and the natural imperfections which are inherent in every human mind."*

But while mistakes may result from ignoring or making too light of the symptoms and complaints of patients, the remarkable absence of symptoms in some cases of advanced organic disease shows that the only way to avoid mistakes of omission is to make a complete physical examination in every case which comes before us.

*W. W. Keen, M.D., in Da Costa's "Physical Diagnosis," 1911.

†Wilmot Evans, M.D., "Medical Science of To-day," London, 1912.

*"Mistakes," by Byrom Bramwell, M.D., *The Lancet*, July 29, 1911.

In the case of experienced practitioners the incomplete examination of patients, due to hurry and hasty conclusions perhaps, is probably the most common cause of errors of diagnosis, but while this may be so there is no excuse for it.

In the case of the less experienced their very ignorance ought to impel them to great care and be an incentive to lead them to seek expert advice, through consultations, and also to compel them to take every opportunity to improve their knowledge in the necessary diagnostic technique.

In these progressive days no one can afford to be lacking in general medical knowledge, and never was the opportunity for self-improvement greater and more easily obtainable, and at so little cost of time or money as at present. The numerous excellent general, medical, surgical, and special periodicals; the wonderful variety of books in every department of medicine; the frequent opportunity to hear every possible branch of the science discussed in medical and allied societies; and the number of public clinics and practical post-graduate schools throughout this and other countries, open the year round and in charge of experienced up-to-date teachers in all departments of medical science, leave no excuse for the general or special practitioner not to add to his knowledge, and at least to equal the standard required by law and the necessities of honest practice, even though the general average and standard is becoming broader and higher every year.

That the profession at large is rapidly realizing its needs and opportunities is shown by the large and ever-increasing number of practitioners, of every grade and standing, who patronize the various clinics and post-graduate schools and technical laboratories.

It may be of interest at this point to mention that an inquiry, recently, of the librarian of The New York Academy of Medicine showed that there were on its shelves thirty-seven volumes on physical diagnosis, thirty-one volumes on surgical diagnosis, thirty-five volumes on chemical, bacteriological, and microscopical diagnosis, and 125 volumes on general diagnosis; that about half of them had been written since 1900, that each copy was either a last, or a new edition, and written by a different author.

In addition there were about as many more volumes on auscultation, percussion, uranalysis, blood, and radioscopy, or over 400 volumes devoted solely to diagnosis in some form or other.

Evidently physical, clinical, and technical diagnosis is becoming not only popular but more and more exact and scientific. How different, how difficult, and how expensive it was to obtain such opportunities and knowledge when we gray heads first began the study of medicine years ago.

In pleading for the physical examination of a given patient is meant an examination as complete as may be necessary to determine not only the nature of the disease from which the patient suffers, and seeks relief, but also to discover any other existing organic disease present, even though it has not yet caused noticeable symptoms. That means to have the patient partly or entirely nude, from head to foot, as necessary to inspect and examine closely any external part, or any internal organ, that can be reached and may possibly be affected, or injured, and also to make such further examination of the urine, blood, sputum, gastric contents, feces, vaginal and urethral discharges, and spinal, pleuritic, or other effusions as the symptoms suggest, and as may be required to determine the disease or diseases present. Naturally it would rarely be necessary to make such a complete general examination, yet I have seen only recently a little girl of eight years, in a certain research hospital, where nearly all of the means suggested had been looked into in a most scientific manner and no definite diagnosis made, and the little girl was held for further examination and observation. It only goes to show the great care and skill deemed requisite by physicians of the highest scientific qualifications.

It would surprise the average practitioner to observe the thoroughness and the detailed minutiæ exercised and the time expended, not only by the departmental and clinic staffs, but also by our greatest clinicians and teachers, busy men, in our public clinics and hospitals, in order to properly and fully study the cases coming before them, and which was considered necessary in order to make a correct, positive, or differential diagnosis.

It can hardly be expected that in the limited hours of office practice, or in the short time left each day to make calls, that a busy practitioner can make an extensive examination on the first consultation as outlined, but he can at least bare the chest, or abdomen, or extremity, or make such orificial examinations as seem to be necessary to determine whether he has to deal with a diseased heart, or lung, or a rheumatic joint, or a flat foot, or a sprain, or a fracture, an eruptive disease, or a floating kidney, an abdominal or other tumor (or possibly cancer), or a pregnancy, or a miscarriage, and ectopic gestation, etc.

An ear placed against the clothes on the chest, a pressure of the hand on the covered abdomen, a hurried feel of the pulse, a look at the tongue, and a hasty gunshot prescription, is not only a farce, but it is a crime, and yet, according to report, these things are done to-day, and often comprise the only physical examination, and sometimes even these crude methods of diagnosis are not employed.

It seems unnecessary to say that a specimen of fresh urine should be secured (and at times a twenty-four-hour specimen) and examined for albumin and sugar, and frequently for casts, pus, blood, indican, and other constituents, tubercle bacilli, and lead, as symptoms suggest organic disease of the urinary, or intestinal tract, or lead poisoning, for instance. It is certainly desirable to know whether we have a nephritis, or a diabetes, in addition to another disease, and especially before subjecting a patient to a surgical operation, and yet how frequently the urine is overlooked or but indifferently examined.

I recall several instances where a child, supposed to have had some simple indisposition or an erythema, was allowed to play out of doors, or to wade in the surf and to mingle with playmates, on the assurance of the attending physician that it was not a case of *scarlet fever*, suddenly become quite ill and bloated of face and legs, when an examination of the urine showed marked albuminuria and an inspection of the body a desquamating peeling skin, proving conclusively that it was a case of scarlet fever which should have been diagnosed with a proper examination, and that proper precautions should have been taken.

The cases of nephritis and diabetes overlooked because of a failure to examine the urine are of very common occurrence, and, further, one should not rely on a single negative specimen.

I remember a lesson received when an interne in the Presbyterian Hospital in examining a specimen of urine, as customary on the admission of a patient, of a man admitted for a "white swelling" of the knee joint, and found the urine apparently normal, but before morning the patient had violent uremic convulsions, and a specimen then obtained by catheter was found to be loaded with albumin and casts.

Another point well worth remembering is that in diabetes a morning specimen of urine will not always show sugar present, though later in the day it may show a high percentage.

I have in mind two such cases in patients running from 6 down to 2 per cent. and in a number of instances no sugar was found in the morning specimen obtained from them.

Every modern physician it would seem would recognize the importance of an early and quick diagnosis, and the value of laboratory aids in this direction, especially as shown by an examination of the blood and sputum.

A "blood smear," sometimes the only means of making a correct diagnosis, and which gives so much valuable information to the physician, as well as to the surgeon, seems rarely to be studied outside of hospitals and clinics, and in the practice of experienced practitioners. Sometimes it is the only means of recognizing and differentiating a malarial fever, for instance, running an atypical course without definite paroxysms, and simulating typhoid fever, or meningitis, or tuberculosis, or a pernicious anemia, the latter often mistaken and treated for a number of other chronic diseases.

A "blood smear" is easily taken, stained, and examined, and readily differentiates the various anemias, primary, pernicious, and secondary; leucemia, myelogenous leucemia, etc.; and also the different malarial parasites; filariasis; also the condition of eosinophilia, not infrequently associated with trichiniasis, uncinariasis, and intestinal tenias and parasites, and certain skin diseases.

Anyone can readily make a smear, and if one is too busy to make the examination, or has not the apparatus to do so, it can be done at little cost by physicians and laboratories competent and at hand almost everywhere.

I have heard it stated, as an excuse for neglect, that, in addition to being too busy, it was not necessary to make any special physical examination of a patient, on the ground that ninety odd per cent. of the patients consulting us recovered anyhow, and that the others would die in spite of what we did, or did not do;—certainly an easy way of practising medicine.

Surely no one should raise the objection of being too busy, and if one is not competent to make the necessary physical or technical examination an expert consultant should be called in to examine the patient, and such specimens as may be desirable to have examined, to clear up the diagnosis, should be submitted to a clinical expert, or to a laboratory, for a report.

It is possible now to have most of the clinical or laboratory examinations made for a moderate fee, and in a few hours' time, and time, as in diphtheria, for instance, is an important consideration, and often means the difference between life and death.

Not long since I was called in to see a four-year-old child, one of several of a former patient, and I was told that the child had been ill about six days with what the attending physician, a homeopath, said was tonsillitis, that the child continued to grow worse, and the parents then discharged the doctor and sent for me.

A look at the swollen cyanotic face and neck and the excoriated lip and nose, and the labored breathing, was enough to make a clinical diagnosis of diphtheria at once, and a look at the grayish exudate on the tonsils and fauces confirmed it.

Without waiting for a laboratory report of the smear taken, antitoxin was given and repeated later, and fortunately the membrane promptly began to curl up and disintegrate, and the boy recovered with only a slight palatal paralysis which cleared up later.

The neglect here was in not taking a smear, for the family had suggested the possibility of diphtheria, but the doctor stuck to his diagnosis of tonsillitis and so failed of a diagnosis. There was no excuse for such neglect, for a smear could have been sent to the nearby Health Department office, and a culture made free of expense, and a report received within twenty-four hours.

These thoughts suggest that the time is coming when medical science and practice will become so exact and the examination and treatment so technical that physicians will have to curtail the number of patients they see and the amount of work they do (though that seems to be happening from other causes) and also give more time and use better methods, and finally, we will hope, receive better and equitable remuneration for the services rendered as attending or consulting physician.

This leads me to suggest another vital matter, that is the need and advisability of the more frequent employment of qualified expert consultants in our modern practice with its many complex conditions and responsibilities. The poorest, as well as the richest litigant, person, or corporation, criminal or not, does not fail, either by direct assignment of the court or by personal engagement, to employ able specialists and numerous counsellors when seeking justice or exemption at law, or even in mere business matters, and why should the *physically* sick and we their physicians not do likewise.

I believe consultations are not only helpful to the sick but are also to the attending physician by helping to keep or restore confidence as well as in leading to better treatment.

Further, consultations with expert specialists must necessarily give confidence and encouragement to the physician in attendance and help to broaden his mind and to improve his diagnostic technique.

The ethics of consultations, a stumbling block to some, need not be discussed here, and especially, as I believe, that medical gentlemen of scientific attainments and standing are honorable, as a rule, and can be trusted to safeguard the rights of the practitioners calling them in.

I have had it in mind to write a paper on this subject, practically errors of omission, for some time, but have delayed owing to diffidence and the difficulty of saying anything new. But my experience in the tuberculosis clinics of the Presbyterian Hospital and of the Vanderbilt Clinic the past five years, where so many sadly neglected and unrecognized cases of pulmonary tuberculosis have come for treatment, with the somewhat similar experience related to me by some of my friends has induced me, under pressure of the rules of our society, to write a paper and to give public expression to the views and experiences herein narrated with the hope that they may lead to greater care in the examination and treatment of the sick.

A few years ago Dr. L. D. Bulkley related to us a case which came under his care after the patient had been treated by another physician for a supposed eczema, I believe, and in which the disease present, syphilis, had not been diagnosed for want of thoroughness in the examination.

Dr. Bulkley said that according to his custom in such conditions he had the man stripped of clothing, and on inspecting the body carefully he found the initial lesion, a chancre, on the man's perineum just behind the scrotum where it probably had been inoculated by scratches of the man's germ-laden finger nails.

This reminds me that we must always be on our guard respecting the possibility of syphilis, no matter who the patient may be, and if we cannot always find the specific lesion we may be able to make a diagnosis by exclusion, or by a therapeutic test, or, better yet, by the new and valuable Wassermann test.

In an article published in the MEDICAL RECORD of March 18, 1911, Dr. R. H. M. Dawbarn states that, "the ordinary estimate is that 10 per cent. of the population of cities, alike here and in Europe, are either now syphilitic or have been."

I remember a patient operated upon by an eminent surgeon years ago for a progressive stricture of the rectum, after failure to give relief by bougies. Colotomy was performed with some relief, but the suspicious and alert house surgeon suspected syphilis, especially as the patient was a "fast" woman and a morphine habitué, and he put her on mixed treatment with the result that in a few months' time the stricturé melted away so that the stools were voided naturally and, as I remember, the colonic opening closed up of itself. It was undoubtedly a gumma of the rectum.

Dr. A. R. Robinson has spoken of a patient operated upon by a prominent surgeon, since deceased, who excised the rectum for a supposed cancer, but which was subsequently shown to be a gumma. If either of these cases had had a few weeks' therapeutic test, with specific treatment, a serious operation could have been avoided; now a Wassermann test should be made in suspicious cases.

A year ago, nearly, an eminent physician of this city delivered an address at the opening of an extension to a certain teaching institution, before a mixed audience, professional and lay, and with startling frankness related the following report of a case as showing the need for such institutions. At his request his name is omitted. "Some time ago I was called in consultation by a reputable physician in this city, who does a rather large general practice, to see a patient whom I found *in extremis*. He had a consolidation of the lower and middle lobes of the right lung and was developing pulmonary edema, although he was perfectly rational and conscious. He did not consider himself very seriously ill nor did his physician or his family. His physician had made no physical examination of his chest and did not know that he was suffering from lobar pneumonia. I had serious doubts whether an examination of his chest by his physician would have made any difference in this instance because I doubt whether he was competent to recognize the physical signs of lobar pneumonia. I referred to this case as showing the possibiliteis for harm which lie in the hands of an untrained and incompetent medical man. This instance, which came under my observation, was probably only one of hundreds which would happen during the course of many years of practice of such a man."

Just think of it. The case terminated fatally of course. I think the doctor referred to two such cases, in one the attending had not thought to examine the chest, and in this case the physician, in answer to an inquiry as to why he had not made a physical examination, answered that "he did not have to because he knew and could recognize a case of pneumonia without."

Last July, 1911, I had the pleasure of attending a great clinic on early and late cases of locomotor ataxia by Dr. Henry C. Baldwin, at the Massachusetts General Hospital, in Dr. R. C. Cabot's course at Harvard, and I must say that I have never seen so many cases of that disease in women, as he showed us, and that was the opinion of the members of the class.

Dr. Baldwin laid great stress on the necessity of having all patients suspected of having "tabes" entirely nude, excepting a napkin over the genitals, in order to be able to detect the disease in its very earliest manifestations, and when so stripped the peculiar ataxic gait was apparent to all, and long before the classical signs of Westphal, Romberg, Argyll-Robertson, and Fraenkel,* might otherwise have made a diagnosis possible, though it seemed to the members of the class that Dr. Baldwin could make a positive diagnosis on the irregularity and inequality of the pupil alone.

This shows the importance of making a thorough physical examination of the person, with the body naked, and particularly in such a progressive disease as locomotor ataxia, where early recognition is vital, and especially now that the possibilities of "salvarsan" (606) are looming up as a valuable remedy to stay the disease, if not even to prevent or cure it, if given early enough.

It occurs to me here to remark how fearful some physicians are to ask a patient to remove his or her clothing for examination, or to ask certain questions, and especially of women, more particularly as to their age, possibility of pregnancy, or venereal disease, or to insist upon a vaginal or other necessary physical examination. As Dr. A. Jacobi has said, "there is no sex in medicine," so why fear to ask any necessary question in a proper and matter-of-fact way or fail to insist on such close examination of the person as may be desirable to detect disease.

I could narrate many cases showing inexcusable errors of diagnosis, or no diagnosis at all, because of failure to make a thorough examination of the patient, as herein briefly outlined, and as routine practice, but do not think it necessary to do so, as they must be of common experience.†

Errors of diagnosis in fracture of the base of the skull, where the police, and the ambulance surgeon, also, at times have made mistakes and taken injured persons to the "lockup" as "drunks" are of common newspaper report; and unrecognized cases of cancer of the uterus, and of serious heart, kidney, or lung, or other organic internal disease are so fre-

**Westphal's sign:* Absence of patellar reflex.

Romberg's sign: Swaying of body and inability to maintain an erect position with the eyes closed.

Argyll-Robertson pupil: Loss of pupil reflex to light, but reaction to accommodation retained.

Fraenkel's sign: Hypotonia, a condition found in tabetic persons in which a patient lying flat on his back on a level surface can completely straighten his legs, when at right angles to the body, which can not be done by a normal man, whose knees will be bent when the thighs are at right angles with the body.

†In the paper as read a number of cases showing inexcusable errors were briefly reported, but, owing to the length of the paper, they have now been left out.

quent, the symptoms so plain, and which so often lead to such unnecessary tragedies that it is with sorrow and regret that I even allude to them.

As to cardiac diseases, and tuberculosis, it would seem that if doctors but knew the normal heart and breath sounds, and would take the trouble to bare the chest and listen, they might, at least, recognize advanced conditions of disease. As for early cases of tuberculosis a careful study of the clinical history, with a temperature and pulse record taken night and morning by the patient for a week, ought to make a diagnosis possible, and especially if the bare chest be gone over thoroughly from apex to base, the sputum examined, and a von Pirquet tuberculin test made.

Conclusions.—1. Every active practitioner, I am ashamed to have to say, should be familiar with the common anatomical landmarks and of the general physiological phenomena of the human body and its organs and their functions.

2. No one should attempt to treat the sick or injured without first making a careful physical examination, in every case, as soon as possible, with the patient partly or entirely nude, according to the part affected, and also of his urine, as opportunity presents, and further, as indicated, examine his blood, sputum, gastric contents, and feces, and such other discharges or material as will throw any light on the nature of the disease and be helpful in the making of a diagnosis.

3. As patients present themselves we should determine our possibilities and limitations in the case, and when necessary seek such aid as may be desirable and available by calling in an expert physician, surgeon, or specialist, or if this be not practicable then refer the patient to one competent to diagnose and treat the disease presumed to be present and beyond our ken.

This suggests that whether general practitioner or specialist we should not attempt to "dabble" in every department of modern, general, and special medicine, but limit somewhat our field of work, though it were well that we should have as much special and general medical knowledge as may be possible.

Let us honestly recognize our abilities and deficiencies and make more frequent use of expert consultants and of laboratory specialists, and of their knowledge and skill, not only for the benefit of our patients, but for our own improvement and future benefit as well.

I suppose you will call all of this just preaching. Well, it is, but we need it, and plenty of it, over and over again. To emphasize it I will relate an incident that occurred during the recent very cold spell when a poor tramp of a woman wandered into our church one evening to get warm, I suppose, but on entering the lecture room and hearing the minister speaking she turned quickly, exclaiming, as she went out, "Preachin', preachin', nothing but preachin' every damn place I go."

In closing let me quote and amend an old proverb: "honesty is the best policy," though not because it is politic, *but because it is right, and what is right is best.*

131 West Seventieth Street.

The X-rays in the Treatment of Nephritis.—D. Galausino made a study of the effect of the *x*-rays in the treatment of experimental nephritis in rabbits and guinea pigs, and also in the treatment of nephritis in human beings. In none of the cases was either the circulation or the function of the kidneys favorably influenced by the treatment.—*Il Policlinico.*

THE SEXUAL EDUCATION OF THE CHILD.

By RALPH REED, M.D.,

CINCINNATI, OHIO.

ASSOCIATE IN PSYCHIATRY, CLEVELAND-PULTE MEDICAL COLLEGE CLEVELAND, OHIO; ALIENIST AND NEUROLOGIST, CINCINNATI POLYCLINIC, CINCINNATI, OHIO.

The problem of the sexual education of the child is but one phase of a much broader problem, the sexual education of the adult. The success of the former depends to a degree upon the latter. In general, current and popular ideas upon sex are still crude, immature, and interwoven with error and prejudice. But a gratifying change of sentiment has lately begun to be manifested. One might say that the world has only recently discovered the sexual. At least (if we except that formerly half-hearted attention medical men paid to the generative sphere and its disturbances of function) it is only recently that it has been realized that there were any real problems connected with the sexual—that, as an instance, it could even possess a psychology. First there came the modern gynecologists, a list so replete with honorable names; then the men who, by sincere and conscientious work in an allied field, that of genitourinary surgery, have given that specialty as honorable a place as any in medicine. Darwin and Wallace called attention to the importance of sexual selection in evolution; Weismann and others have studied the germ plasm itself and its relation to heredity. Wilson, McClung, and their coworkers have contributed valuable data to the problem of sex determination. Thompson and Geddes have studied its evolution and appearance in its many and varied forms in animal and vegetable life. Kraft-Ebing broke down the prejudice and paved the way for a more thorough investigation of its aberrations and perversions. Havelock Ellis followed Ebing in a series of studies broader in purpose and method, bringing this phase of the subject to a splendid fruition. Weiniger, so early lost to the world, revealed in a masterly, yet, perhaps, somewhat erratic and one-sided thesis, the innermost essence of the psychology of the feminine. Lastly, in this relation, Sigmund Freud, whom we shall have occasion to mention again, more analytical, more penetrating than any of his predecessors, approaching the subject from the standpoint of the neurologist and psychopathologist, presented the medical world with a series of clinical studies so clearly demonstrative of the relation the psychoneuroses bear to disorders and perversions of this fundamental instinct that his work has already effected a revolution in the treatment of a whole group of nervous disorders by those who have given the subject sufficient attention really to appreciate the importance of his discoveries. The social relation of the sexes is beginning to be discussed in a very frank way in novels and dramas; Ibsen, Shaw, Brieux, and Sudermann leading the way; while Ellen Key, with a remarkable insight, has discussed the ethics of love and marriage. The modern world is at last rubbing its eyes and awakening to a realization of its own impulses and tendencies.

The sexual ideally belongs to the unconsciousness, as it does with all animal life and largely with primitive peoples, but modern man has already long ago eaten of the tree of the knowledge of good and evil, and sex having become with us partially conscious there is now nothing to do, if we would

avoid the dangers of such partial consciousness of this powerful and universal instinct but to bring it more and more completely into consciousness and there boldly face the fact of its existence and solve the problems implied such recognition. *Self-consciousness* in the race as in the individual is ever the foundation of *self-control*. We no longer can obstinately close our eyes to the existence of this vast and universal hunger. One is reminded of the lines of Walt Whitman:

Out of the dimness opposite equals approach.
Always substance and increase.
Always sex.

The sexual is not as it was formerly supposed to be, episodal; it is like the rest of the laws of nature—never repealed. How important then is this question of the sexual education of the child! But immediately difficulties present themselves. Shall such education be accorded through the written word, through the school lectures, or be gained at the mother's knee? The first two, for reasons I shall later define, I do not consider the best methods. But if we expect the parent to educate the child another difficulty presents itself. The parents themselves are uneducated in this respect, and there are difficulties in the way of even the most simple, chaste and well-intentioned discussions of the subject. This is due to two attitudes taken toward the sexual by two classes of individuals; the shocked attitude and the obscene attitude; in other words, there are always some spinsterly minded individuals on the front seats who are shocked, and some frivolously minded on the back seats who are amused. Why is the statement frequently made that it is difficult to discuss calmly and simply the facts of sex with the child? Because outside of meetings of medical societies it is difficult so to discuss them with each other. This attitude of the old-maid (I use this term 'old-maid' ever to express a state of mind, never a state of years) on the front seat and of the young person on the back seat exists in a greater or less degree repressed or expressed in the minds of all of us. Hence as a preliminary to any useful discussion on the subject it is necessary to free our own minds as far as possible from any sexual complexes, pharisaical or obscene, and consider the problems of sex in their relation to human beings with a state of mind as unemotional as the biologist considers the problems of sex in their relation to, let us say, the star-fish.

As a result of this attitude toward the sexual one of the first barriers to be encountered is that of language. The sexual has always been a subject so forbidden, so tabooed that we really have no popular yet proper language of sex at all. Discussions on the subject of sex are carried on in three tongues, two of them more or less foreign to the users of a third. There is first the language of the masses, or as we would express it, the obscene or vulgar. This language was formerly the language of all classes when society was less sophisticated, more childlike minded and direct, as an examination of unexpurged editions of Chaucer, Shakespeare, or any of the older English dramatists will show. Then there is the scientific or technical language, and finally the language of polite society, the language of indirection, innuendo, double meanings, and paraphrasis. Whatever purpose this third tongue may serve its users, its tendency toward the corruption of the English language must be admitted, since it continually tends toward the perversion of non-sexual words to sexual usage. As witness the frequent perversion of such English words as nice, pure, clean, good, virtuous, etc., to a limited sexual connotation. Even such a useful word as "honest" has not escaped. As with many, and particularly, I believe, in England, an "honest" girl does alone not mean a girl who will not lie to you, or steal your purse, or rob your house, but a girl who does not indulge in sexual intercourse outside of the marriage relation. What is the meaning of this tendency? One explanation is just ordinary hypocrisy; another is a universal fear of the sexual in words and even in thought. The psychoanalyst will resognize the origin of this fear. But still another and better reason is the sacred and extremely intimate and personal character the sexual acquires for many. In almost all primitive religions the sexual and the sacred are nearly synonymous terms. Christianity in strong reaction against the earlier religions eliminated totally the obviously sexual, and going further, bitterly condemned all worldly pleasures. There was implied in the sexual a very old and very worldly pleasure, hence the whole business was given an extremely bad name by the Fathers of the Church. It constituted one of that great trinity of evils—the World, the Flesh, and the Devil. For those who look upon the sexual as *essentially* evil there is no problem to be discussed, because from that religious point of view, the essence of which is to condemn everything which brings pleasure or happiness in this world on the ground that happiness in the next will therefore be augmented, strict asceticism for everyone is the highest ideal. But the world has gotten beyond this or given up the hope of its attainment—as one pleases to express it.

But to return to the first-mentioned of the three languages of sex, the obscene. What constitutes obscenity? Obviously not the language itself; there is nothing essentially evil in that, since it is nothing more than merely words used to express certain ideas of mental images we all of us possess. Is it not rather that light, frivolous, and contemptuous attitude toward the sexual which the use of such language almost always implies? Sex is not an object to be dealt with lightly, frivolously, or contemptuously. It is a very serious, important and for many a very personal and intimate affair. Yet we all of us, because we belong to a sexually mis-educated generation, possess that contemptuous attitude toward this instinct in a greater or less degree, and we will never be able to free our minds from it entirely. In witness of this I refer the reader to the conversation of any group of men of the world, no matter what their occupation or social status may be, in certain moments of mental relaxation. Many women would be surprised if they could hear the sallies of wit and humor that on such occasions flash back and forth; but they would be no more surprised than many men would be, if they could overhear the conversation and gossip indulged in at certain card clubs or even some sewing circles devoted to the manufacture of garments for the heathen. Hence modern thought is interwoven with the obscene or the fearful way of regarding sex largely because of the manner in which the present generation acquired its early sexual education. That education was in the vast majority of cases the education of the gutter. Even when we do attempt some sort of rational education of the child along these lines we usually do not awaken to the need of such instruction until sex

has acquired for the child a degraded and obscene connotation. Then for most parents the factor of shame has entered with its inhibitory power and erected an almost insurmountable barrier between themselves and the child. Is there any wonder so many marriages are unhappy when so many individuals take so contemptuous an attitude toward the central function of marriage and have been taught to believe, by indirect suggestion and tactless instruction, in the essential sinfulness of that function.

It was formerly believed that prior to puberty the sexual instinct was dormant or entirely non-existent. But, thanks to the labors of the psychopathologists, a few students of the psychology of adolescence, and principally to the studies of that leader in the field of abnormal psychology, Sigmund Freud, we now know that this instinct is present, but, of course, in an unconscious form, even in the very early years of a child's existence. It is during these years that frequently the foundations for perversions are laid.

We thus see that in the great majority of cases it is impossible to keep such education away from the child, because, even if carefully secluded, it will still be subjected to a kind of autoeducation, an education which tends to foster and keep awake those very instincts, the development of which it is designed to restrict by the policy of no education at all. This is the unanswerable argument to those who would oppose the education of the child in sexual matters on the ground that by so educating it we run the risk of stirring up traits and tendencies which would normally be dormant for many years. Yet where a custom is of ancient origin and adhered to alike by cultured and ignorant, rich and poor, there is a strong probability that there is something to be said for it, and that it should not be too readily condemned or too ruthlessly swept aside, even though in individual cases its effects may be shown to be lamentable. Hence, if the reader expects from me any impassioned demands for the immediate introduction into the public schools of lectures on sexual science and hygiene, he will be disappointed. One of the advantages of the method of sexual education of the child that I shall propose is that, in contrast to public school lectures, it does not ruthlessly disregard the feelings of those who believe that sex is entirely too intimate and personal a matter to be discussed except, perhaps, between husband and wife, parent and child, or physician and patient.

Perhaps the most serious objection brought against any suggestions looking toward the enlightenment of the child in this respect is the view frequently expressed that it will rob the child of that delightful innocence, the most charming quality in the child character. But in answer to this we may well ask ourselves just what constitutes innocence. Is it synonomous with ignorance? To a certain degree it must be admitted that it is. But innocence is not wholly composed of sexual ignorance. One of its chief components is any kind of ignorance and those quaintly *naïve* questions of the child so indicative of its innocence may represent ignorance upon any subject. We do not hesitate to deprive the child of many other forms of ignorance for the sake of its innocence, then why hesitate to deprive it of sexual ignorance when this ignorance may eventually prove to be, instead of a mere character *nuance*, a treacherous foe. But innocence is not merely ignorance, it consists rather of a certain unspoiledness of outlook upon the world, a trustfulness that in itself often disarms aggression, and a simple, frank and direct method of expression and appeal. It is represented largely by an absence of indirection in obtaining an end and by an ability to enjoy the simple and minor pleasures of life, and an appreciation, as the Japanese have expressed it, of "the *ah!ness* of things." It represents rather an absence of cynicism and sophistication than an absence of ignorance. The world destroys innocence much more quickly by hurting, betraying, and saddening than it does by enlightening. Its most essential characteristic being a simple truthfulness and a confiding trustfulness, I believe that the average parent's attitude toward the sexual question destroys innocence in the child much more quickly than would a reasonable degree of enlightenment, since that attitude is neither a truthful nor a trustful one. And the attitude of the child is by suggestion quickly acquired from the attitude of the parents. But one of the qualities of innocence is no doubt to a degree an ignorance of vice. Still it is not necessary in teaching a child or any one, for that matter, a few simple facts about sex, to instruct it also in vice (I am not even in favor of warning a child against masturbation, unless there is reason to suspect the existence of the habit), any more than it is necessary to teach school children pathology merely because we teach them physiology and hygiene. Rather what is necessary is that complete confidence between parent and child that will enable the parent to recognize very early the outcropping of vicious traits.

But there are some who say that by taking away from the young the mystery of sex we take from love all its beauty and sacredness. This may be in part admitted, but the perverted education the child at present receives does this, we feel, much more quickly. Because of this very fact of miseducation it is doubtful if there are many people who are able to see anything very beautful or sacred in any phase of sex. If there are any such factors in sex it will remain for a generation with a much higher, purer, and nobler viewpoint than our own to properly appreciate them.

I will not burden the reader with a catalogue of the unhappy results of our present prudish and puritanical policy of attempting to keep the young steeped in sexual ignorance. The specialist in genitourinary disease and the social worker have, perhaps, the longest reports to file in this connection. I wish rather to call attention to certain disastrous consequences unnoted in the great majority of papers written upon this subject. I refer to *the mental and nervous disorders which may develop upon a basis of certain sexual incidents, misunderstandings, and perversions to which the child may be subjected, usually between the years of six and ten.*

In the absence of all explanation or education, yet frequently subjected to the influence of somatic turgescence and sexual fancies incident to the physical and mental development of many of the most normally constituted, is it strange that sex, which even for the adult possesses numerous contradictory elements, takes on for many children the aspect of a great mystery, not unlike the mystery that with the adult surrounds the nature of Deity? This soil of concealment is admirably adapted for the development in the child mind of many bizarre ideas, strange fancies, and hidden entanglements. Given certain peculiarities of temperament, particularly in girls, and with that certain peculiarities of

the first encounter with the sexual problem, such encounter is frequently able to produce a grave neurosis offering many difficulties to the neurologist, when, perhaps, after several years, the case comes under his care. The possibility of the dependence of a psychoneurotic state in, we will say, a patient aged twenty-nine, upon a sexual complication incident perhaps to the age of nine, is not at first obvious or even credible to some. Prior to the work of Freud such an etiology was never suspected. The reason for this was that the experiences constituting the start of the psychoneurosis are always lost to memory, and it is only by the method of psychoanalysis that a memory of the incident or misconception can be revived, and it is not until such revival has been effected and the repressed memories are again assimilated in consciousness that a cure is possible. This has been abundantly proved by numerous psychoanalyses, and my own cases have only verified for me the findings of others who have experimented with this wonderfully fruitful method. The reality of these revived memories has been questioned by the opponents of psychoanalysis, but when a case history is finished in detail the internal evidence furnishes abundant proof of their validity. Freud and Jung have reported physchoanalyses of developing psychoneuroses in children of four or five in which a direct verification of the relationship between the sexual misunderstanding and the nervous symptoms was possible (Jung, *American Journal of Psychology*, 1910). I have been fortunate in carrying an analysis to a successful conclusion in a girl of twelve, verifying the relationship her hysteria bore to certain sexual incidents occurring only a few weeks prior to the time she came under my care.

Parents are frequently afflicted by a curious delusion. Other people's children may be vicious, but theirs are always innocent. In such cases it is not usually the children, but the parents, who are the poor, innocent creatures. The children are wise, and if pornographic literature has by chance fallen into their hands, sometimes wise with the wisdom of the ancient Greeks and Romans. Wise, indeed, but usually with a perverted, wrong, and obscene wisdom. It is the parents who must first be educated.

A case history will here illustrate this point as well as some others that I have attempted to emphasize. It should be understood that this and the other case histories cited in this paper make no pretense to completeness. If I should report any one of them completely it would require more space than I have allotted to this entire paper. I have rather selected and isolated certain incidents in each case, not sufficient as an explanation for all of the symptoms, but sufficient for the purposes of illustration:

Lida S.—Came under my care at the age of 16. She was having severe convulsions at intervals, was confined to bed by an hysterical astasia-abasia, and contractures; anesthesias were marked, and she suffered from a persistent anorexia. A psychoanalysis revealed among others, the following complication. At the age of 13 she had acquired some ideas of birth, but possessed a very slight knowledge of the function of the male in reproduction. One day some girl friends told her stories of what a terrible disgrace it was for a girl to have a baby without being married. Such an incident occurring in her neighborhood, and the resulting gossip also impressed her deeply. Her mind reverted to an experience (innocent enough in itself) she had had some months before with a boy acquaintance, and an unjust and tactless accusation that followed it. She conceived the idea that she might, any day, almost any hour, give birth to a baby. For two years during the most critical period of her intellectual development, she brooded constantly over this idea. Her case was diagnosed almost everything from rheumatism to dementia præcox. To say nothing of the loss of schooling due to her prolonged invalidism, the mental damage done will never, perhaps, be entirely reparable. When her mother was informed of the state of affairs she was inexpressibly shocked. "I have always," she said, "made every effort to keep Lida absolutely innocent and pure. I had no idea that she knew anything at all of such things." And the daughter at that time a girl of eighteen!

Now, as in different children—according to their environment, general education and psychosomatic sexual development—sexual curiosity arises at different ages, such education as we are considering must be the most highly individualized of all education. The results of too little or too much may perhaps prove equally unfortunate. Hence, since I have seen only lately renewed demands for the embodiment of a course in sexual physiology in the public schools, I am compelled to protest against any such step. There are many educators in the United States who possess an excellent knowledge of child psychology, as far as such knowledge goes, but very few, if any of them, have any knowledge at all of psychopathology or the various anomalies of sexual development in the child, and without such knowledge no one is in a position to speak with authority on the subject at all. One might almost count upon the fingers of the two hands those who are, and they are not educators by profession, but physicians. It would thus seem that at least the request that before such a step be taken the subject should be much more thoroughly and widely discussed than it has been, is amply justified. No doubt in time a place for school education in this respect will be found, but personally I feel that the time is not ripe.

In Germany, school courses in sexual physiology are already in operation. Dr. Zenner has reported good results from a series of experimental lectures he delivered to the children of the Cincinnati schools. (Education in Sexual Physiology and Hygiene, Phillip Zenner. The Robert Clarke Co., Cincinnati, 1910). It may readily be conceded that while in school we teach children so many perfectly useless things (to describe the course of the Yangste-Kiang River, to bound Afghanistan, to name the chief industries of Iceland, and give the answer to many other curious questions), we yet fail to teach them to meet sanely and rationally many of the ordinary complications that arise in real life. It is a mistake to send children with no knowledge at all of sex, or with only the crudest and most perverted sort, out to battle with Life, Love, and the World. Still with all this certain objections occur to one, particularly where it is contemplated that these lectures shall be delivered by the teachers themselves. Our teachers being most young girls scarcely graduated from the age of gum-chewing and giggles, or prudish and superannuated spinsters, are in the main not fitted to teach anyone anything; much less, since they are in general quite ignorant themselves of the true facts of sex, are they fit individuals with whom to entrust this

delicate task. Another objection is that if the sexual education of the child is attempted as a part of the school curriculum, it will but further increase the intellectual estrangement between parent and child that we have already pointed out as being unfortunate.

Now, the thing to be desired with reference to the main topic under consideration, is the prevention of the development of an unhealthy imagination in the child, because the more such imagination is indulged the more possibility there is of its assuming the nature of an erotic stimulant, and hence favoring an undesirable and premature somato-sexual development. Such sexual fancies, acting as an erotic stimulant to the somato-sexual sphere do, in fact, constitute a form of masturbation, and result to some degree in the neuron exhaustion we know to be consequent upon the more direct form of this habit. Because it has a physiological origin the child's curiosity about sex is not comparable to other forms of child curiosity, such as the mechanism of a watch, or that unanswerable conundrum they not infrequently propound (in reply to the inadequate "God made you" explanation of their origin), "Who made God?" It is a more persistent curiosity and is sustained by and the product of actual, somatic, sexual excitation, which we know may be present, notwithstanding all absence of any external factors tending to awaken it. Because of this rise of a diffused sexuality prior to any somatic localization of the impulse, the child may develop a high degree of psychosexual curiosity prior to any somatosexual feelings; or in some children the reverse of this order may represent the facts. It is just because children differ so widely in this respect that the highest degree of individualization is necessary in their sexual education. In lectures questions cannot usually be freely asked or false ideas corrected. The lecturer is compelled to take such a warning attitude and exaggeratedly moral tone that there is the risk that with certain susceptible children, particularly those who have suffered some sexual experiences, the development of morbid fears may be favored. Much harm has already been done in popular books on the subject by the grossly exaggerated pictures of the supposedly horrible results of masturbation. Most books and lectures also indulge freely in generalities and metaphysical expressions not suitable for the understanding of the child. In the absence of useful information, there is much vague talk of honor and purity, and in this respect books of the "What a Young Girl Should Know" type are usually indefinite and absurd. When plant reproduction is used as an illustration it is difficult to see how the child can appreciate the mysterious shift of scene from plants to man. The question of when impurity becomes purity is always lightly passed over. And often, because of the difficulty of explaining how the marriage vow converts impurity into purity, black into white, bad into good, even the true nature of marriage is left unexplained. A patient of my own, age twenty-four, had heard something about vice and purity and had been taught that only the lowest and most degraded people did certain things. She therefore believed that marriage meant no more than a mere living together in a brotherly and sisterly fashion. She was profoundly shocked by the mere thought that her married friends and relatives might be guilty of what she had always believed was so depraved and sinful. An abnormal fear of and dislike of even thought of marriage was in this case the result of such miseducation.

In many cases where, in the course of a psychoanalysis, it has been necessary to revive memories of childhood it has been found that often children have not believed in the mythical explanations of their parents for a long time prior to the parents' knowledge of the fact. They have nevertheless pretended to. We have known of instances where children have for some time even pretended to a belief in Santa Claus because they imagined that they might gain an advantage thereby. Once, however, the child becomes aware of the deception that has been practised upon him, particularly with respect to sexual questions, the harm has been done, because to a greater or less degree his confidence in his parents has been forever lost. He will no more come to his parents with any questions. There are two reasons for this attitude; the first is the obvious one that he cannot, or feels he cannot, expect any true information from them; the second is that the child has by this time usually been infected through suggestion with that false modesty and abnormal shame which surrounds the whole subject. In this respect Ernest Jones has said "The organized conspiracy of silence is soon noticed by the child, and he is subjected to a mass of suggestion all the more potent for being indirect, which teaches him that the subject is taboo, mysterious, improper, peculiar and essentially wicked." ("Psychoanalysis and Education," *Journal of Educational Psychology*, November, 1910.) The very miseducation thus given the child erects a barrier which prevents him from attaining a true education. Furthermore, it may be pointed out that the average parents' attitude toward the whole subject is one that is so essentially impure, prudish and shameful that, partly for this reason and partly because they have no language that the child can understand into which to cast the subject, any profitable discussion of it between parents and children is usually an impossibility.

It is a mistake to teach children that there is anything particularly sacred, or, on the other hand, anything particularly sinful in the facts of sex in themselves. Again, the enlightenment should not, as Jones has remarked, consist alone of warnings and forbiddings with the risk of making the subject for the child one of shame, guilt, remorse, and terror. It should rather emphasize as far as possible the constructive, the beautiful, and the idealistic viewpoint.

The very young child rarely is curious with respect to more than the eternal question (particularly with little girls) as to where babies come from. This question will often be asked even by the child of five or six. It should be answered as simply as possible. Later, tendencies toward autoerotic stimulation may be inhibited by a tactful warning. At twelve or thirteen the child should be prepared for the onset of puberty, and in girls the menstrual function explained. After puberty it is usually impossible to conceal from children the function of the male in reproduction. Most boys are familiar with that any way at the age of ten. Still later, as a preliminary to marriage, both the young man and young woman should be accorded more detailed information in sexual hygiene.

More knowledge on any subject than can be usefully applied tends to a paralysis of the will, more knowledge on the subject of sex than is necessary tends to a morbidity of imagination.

Hence, while we are frequently told that a little knowledge is a dangerous thing, situations may be imagined where too much knowledge can be equally dangerous. Those who object to any sexual education of the child instinctively feel the danger of imparting too much knowledge of sex prior to an age at which it may be presupposed that the child has acquired strong ethical ideals. We have only to note the way in which the average child will pull apart and investigate anything from a captured fly to a doll or toy watch to see its "insides," or "how it works," to be made aware that the child is instinctively given to research and experimental investigation; incoordinated of course, yet with many children such an instinct is quite as strong as that to be observed in the experimental physiologist or other laboratory worker. Hence it is necessary to point out that it would be very unwise to impart to the child any more knowledge of sex than the child's spontaneous instincts lead it to desire, just as I have in foregoing discussions pointed out that it is unwise to attempt to repress and evade the natural desire for such knowledge that arises instinctively. There is much to know about sex that even parents do not need to know; and it is doubtful whether some of the information to be found in Kraft-Ebing, or certain volumes of Havelock Ellis, is necessary even to the average physician. But it should be remembered that *what is taught, be it ever so little, should be open to no misunderstandings.* Another case comes to mind in this connection, one incident of which was as follows:

A young married woman suffering from an anxiety neurosis was referred to me by Dr. Wilms. Analysis revealed the fact that at an early age some attempt had been made to instruct her in the process of birth, but owing to a misunderstanding she conceived the idea that birth took place by way of the umbilicus. Her mind was never disabused of this idea, until one day a few months following her marriage she was called, in an emergency, to assist a neighbor woman at childbirth. The revelation of the true nature of parturition produced a fear of having children, which in turn excited a fear of intercourse which, in conflict with desire, constituted one factor in the development of the neurosis from which she suffered.

The question as to who shall undertake the sexual education of the child presents itself. My personal opinion is that this, at least in the case of young children, should be the mother. She should be stimulated to undertake such education by her physician. Many prejudices on the part of the parents will undoubtedly have to be overcome. This can be accomplished by the tactful physician, not so much by a formal talk with the mother, as by the passing observation as opportunity offers of the dangers incident to permitting children to grow up entirely ignorant of sex or imbued with fanciful ideas. The younger the child the easier the task of such instruction. Books and pamphlets are useful, but they should be written for the adult, not for the child. They should be reinterpreted by the mother to the child. The words to be used should be plainly set down so that vague generalities may be avoided, since this is the principal defect in many books already written with this end in view.*

*Theodore Schroeder has wisely remarked that "these books are sold on false representation, more or less definitely made, that they will give some helpful and detailed information upon one's concrete personal problems. Instead of answering the questions which young men and women want answered and have a right to know about, the purchaser receives a little moral sentimentalism, some stupid and often truthless dogma, which, together with some that are really true, are promptly disregarded, because no convincing reasons accompany the information. After the reading of such "purity" books, so well filled with vague and mystifying phrases, which mean absolutely nothing to those who do not already know what is sought to be hinted at, one is convinced that he has been robbed of his money without being enlightened, and the young come from the reading of these books feeling more mystified and helpless than ever before over the personal problem." "Obscene" Literature and Constitutional Law, 1911.)

The language I should say ought to be the ordinary language used between physician and patient, perhaps somewhat simplified. The whole problem is a critical one. It is one that is not exclusively pedagogical, but in many of its phases peculiarly medical. Hence the medical profession should not remain indifferent to its duty in this respect and stand idly by, relinquishing the problem to others less fitted to properly deal with it.

I conclude with some brief notes taken from my case histories to further illustrate some of the points I have tried to emphasize. The sexual ignorance is but one factor in these cases, yet it formed a necessary groundwork. Many other inner conflicts and complications unnoted here must arise in after years to bring the disease to a full bloom.

(1) A girl of twenty believed that she had no knowledge of how babies were born until one day on a visit to a young married friend who had been recently confined she was treated to a vivid and dramatic recital of the details of a difficult and dangerous labor. At the conclusion of the story she fainted, was taken home and confined to her bed for some time, the real cause of her symptoms undetermined. This incident constituted what Janet has termed a psychic trauma, but a psychoanalysis according to the Freudian method revealed that it had merely served to light up, as it were, a neurosis that had been smoldering since childhood, the latter also being based upon sexual misunderstandings and a very early development of autoerotic tendencies, quite unrecognized by her parents.

(2) A nurse, aged twenty-eight, consulted me in the summer of 1910. Her life since childhood had been made peculiarly unhappy by the presence of obsessions in the form of religious and other doubts and a constant fear of infection. Even as a child she could remember her mother scolding her for so frequently washing her hands. This fear was for her peculiarly disadvantageous in that it interfered greatly with the practice of her profession. She was very religiously inclined and possessed an abnormal abhorrence of the sexual so that a psychoanalysis presented in her case unusual difficulties. However, I may say that her fear of infection had, in part, the following origin. In her early childhood she was erotically excited by certain incidents to which children are occasionally subjected. These passed from her memory, but a few years later some attempt was made to explain to her the function of the male in reproduction, and the reproductive processes in plants were used in illustration. She conceived the idea that germs from men or even animals were or might be carried in the same way, and she began to fear that she would conceive. She thought everything that she touched was perhaps contaminated in this way, and she devoted a great deal of her time washing her hands, clothes, and underlinen. Gradually, through repression,

she forgot all about the original fear, but it still found expression in consciousness through the process of supplantation or transvaluation as a fear of any form of contamination. This at first concerned itself with possible contamination from plants and flowers, then from insects, then poisons, and finally, when she became a nurse, it took the form of an abnormal fear of bacterial infection or poisoning from the handling of antiseptic solutions and tablets. Some ideas of the difficulties the case presented may be appreciated that of all her early fears and their antecedent experiences she had at first absolutely no recollection, so deeply repressed in consciousness they had been.

(3) This case I shall cite in illustration of the confused ideas the young girl may acquire as to the nature of virtue and purity. Miss M., aged thirty, was referred to me by Dr. Ambrose Johnson, to whom she had been sent for an ovariotomy. He suspected her to be hysterical and referred the case to me for further investigation. I shall not attempt to catalogue the vast number of morbid symptoms she had suffered from since her fifteenth year. They were scarcely greater in number, however, than the physicians she had consulted. She had had one sojourn in a private sanatorium, and another in an insane asylum. The morphine habit in a mild form was another incident of her psychosis. She was homosexual, but the chief symptoms for which she sought treatment were *angst* (anxiety) attacks, convulsive seizures and an anorexia. If I should transcribe the notes I have on the case without any elaboration they would probably cover some twenty sheets of typewriting. Resistance to the expression of many of her painful ideas was so strong that she was unable to utter them and was obliged to write them, a few words or a sentence at each interview.

Incestuous incidents usually between brother and sister are probably not so rare in child life as is generally believed. When they do occur they are usually episodal and occasion no ill results unless they happen to come strongly into conflict with other complexes of circumstances or ideas later in life. Analysis revealed that two such incidents had occurred in the life of my patient. She was at the time aged nine. During the second experience she was by her aunt discovered *in flagratio*. Both she and her brother were treated to a sound thrashing, but in addition the aunt, who was a most moral, stern, and hard type of woman, told my patient that she had forfeited her virtue, that no man after that would be willing to marry her, and that her life was ruined. The little girl took this quite hard at first, but as time passed and she was not struck by lightning, and the sun kept on shining, and she found that she could still be happy and contented at her play, she began to wonder just in what the awful ruin consisted, and finally, perhaps sensibly enough, forgot all about the incident. A few years passed and a traveling evangelist visited the country town where she lived. He preached vigorously against all kinds of sin, and particularly sins of the flesh. She now contracted that malady known as religious conversion, and she had it very bad. She began to hear from other sources of the great importance of virtue and chastity. She thought again of her childhood misfortune and became intensely depressed. She read her Bible almost constantly, but began to be tormented by sexual desire. This to her mind verified the idea that she had now acquired to the effect that she was totally depraved, innately wicked and eternally lost. The thought of what she considered to be her one great sin finally became too painful to bear and she put it out of her mind, never thinking of it until fifteen years afterward she came under my care. Her family took her to a physician, who said she was anemic, and prescribed iron, but she got no better. Other incidents arose to complicate the situation. Her fifteen years of invalidism marked by a few remissions had now fairly begun. The analysis of this case required over a year of careful study. It may be of interest to some who are of that type desirous of having case histories as well as novels end happily to know that her aunt's prediction failed of fulfillment. Following her complete recovery, she has married successfully and happily.

437 West Seventh Street.

SPECIFIC TREATMENT OF PYOSALPINX.*

By H. J. FARBACH,

LOUISVILLE, KY.

My experience recited in this paper has covered about four years, and has been confined to my private practice. This manner of investigation has serious drawbacks and some advantages. The most serious drawback is the limited number of cases one sees in any one line. The great advantage it offers is clinical experience in a better class of patients, who will follow instructions better and more intelligently; and then one sees the patient until time of dismissal, while in clinical work there is often doubt as to the final result, because of the disappearance of the patient.

Ever since the advent of antisepsis and asepsis on practical grounds the gonococcic infections of the female generative tract have offered a great field to the, I might say, radical surgeon. He sacrificed the sexuality of the woman with little or no hesitancy and claimed a successful result as soon as his skin incision had closed. In consequence, probably due to the general lack of knowledge of things sexual among women, they have raised little or no objection to such operations. If, on the other hand, the same sort of procedure had been directed toward the male members of the family, the operation would have been not only decried but absolutely refused. The standard saying of men that, like the Indian chiefs, they would be buried with their implements of combat, dates far back in the shadows of history.

The tube in the male is long and tortuous, its current is against gravity and its final opening is into a small restricted cavity. In the female the tube is short and straight, its current is with gravity, and its final opening is into a large free cavity. In regard to blood supply and return circulation, the advantage is all with the female.

One argument is that the small constricted isthmus of the female tube readily closes when inflammatory action begins, thereby leaving but one exit for the rapidly forming pus and that one into the abdominal cavity. The examinations I have made of the adnexa that were removed in recent or chronic cases have in the vast majority of instances shown that this portion of the tube was not closed and it was possible to force pus or fluid through it with very little pressure.

But in the instances where the pus is forced into the free peritoneal cavity, nature produces here a greater resistance than anywhere else in the body

*Read before the Louisville Clinical Society, January 23, 1912.

and against one of the most liable of pathogenic bacteria. In fact, so successful is her fight that to-day the surgeon advises postponing the operation until the acute process has subsided.

An argument why little or no operative procedures were used in the male, was formerly, that there was no true pus formation in orchitis and epididymitis, but recent investigations show that in every instance miliary abscesses, and sometimes an abscess of considerable size, are present.

The results I report are based on twenty-five cases of acute and chronic variety. My initiation into this work did not come from any celestial influence nor was it the result of scientific deduction. Case No. 1 was forced on me, so to speak. A young unmarried lady who had loved well and passionately but not wisely, especially from a sanitary standpoint, consulted me with a pelvis that had proven an ideal place for the cultivation of gonococcus. After an examination, an operation was advised, but refused as it had been before, on the grounds that it would necessitate a confession to her family, which she positively refused to make.

At this time I was obtaining some very happy results from the administration of the vaccines and serums in complicated and chronic gonorrheas in the male and suggested this line of treatment to the patient, promising her, however, nothing. The results were almost phenomenal. The record of this case shows that on the third day after the first injection of vaccine the patient stated there was less pain and pelvic tenderness than she had known for three months. Within less than one month she could assume any position and twist or bend in any direction without the least pain or inconvenience.

I have divided these cases in acute and chronic, considering any case chronic in which there have been one or more attacks of pelvic pain associated with rise of temperature and general malaise.

The etiology and pathology of these conditions are too well known to require discussion, but one fact that must not be lost sight of is that the chief offending microorganism, the gonococcus, is one of the most, if not the most liable, of bacteria that are infectious to the human. Outside of the human body, even under the most favorable of circumstances, in the majority of instances it is hard to cultivate and is prone to undergo autolysis. Almost any germicide or antiseptic will destroy it in a short time if brought in direct contact with it. Fresh blood serum destroys it even after strong inoculations.

The mode of injection in all of these cases was direct contact followed by careless, improper treatment of a vaginal, cervical, or bladder condition. I cannot help feeling that the female generative tract is not as liable to gonococcic injections as the male. In my own experience I have seen numbers of instances where the husband had for years chronic prostatitis or vesiculitis, still the wife shows no signs or symptoms of the disease. In other instances there is proof of the presence of the gonococcus by the subsequent ophthalmia neonatorum, but in some of these cases the mother shows no clinical evidence of the disease. The sexual toilet may explain this to a certain extent, but not always.

The clinical history in these cases was the classical book picture of tube and ovary inflammation both subjectively and objectively. As to the clinical types I have simply made the distinction of acute and chronic. In some instances the condition was unilateral, in others bilateral. I designated those acute in which the present attack was the initial one. The treatment, however, does not vary in the two conditions.

In regard to diagnosis I wish to say a few words about a procedure which I began two years ago, and thought it original, until I read a report published by Schwartz and McNeil in the *American Journal of the Medical Sciences* of May, 1911. This procedure is the complement fixation test in the diagnosis of latent or unsuspected gonococcic infections. The same reagents and technique are used as in the Noguchi modifications of the Neisser-Wassermann-Bruck reaction, except of course in the antigen. In my investigation I used a mixture of stock gonococcic vaccines and some cultures grown in my own laboratory. In brief, my results were that in some instances the reaction when positive was a great aid in diagnosis and could be depended on as shown by results obtained after treatment was instituted. In other instances I obtained negative reactions when I knew positively that I had a gonorrheal infection.

In every instance in which I had an infection through which I could obtain a culture, and used this culture as an antigen. I got a positive reaction. I was experimenting with a polyvalent antigen when Schwartz and McNeil reported their results along the same line. They had experienced the same difficulty I had, that in some instances of positive injection they obtained a negation reaction. They found, however, that by using an antigen made of a large number of different cultures and strains of the gonococcus they obtained positive reactions in every known infection and it was therefore more dependable as a diagnostic measure.

These results are valuable for two reasons. The most important perhaps is the sustaining of the contention of Rogers that there are different strains of gonococci which produce varying antibodies, and that this must be considered in the making of antigonococcic serum. The second is that it gives us an aid in making a diagnosis of obscure lesions in joints and the genitourinary tract.

I might mention here that these investigations in my hands have proven that the injection of dead bacteria into the human body is followed by the appearance, in the blood stream of the injected individual, of antibodies specific toward the injected material. Knowing, as we do, and as has been proven by these investigations, that the different strains of gonococci produce different antibodies, we appreciate that more good is to be derived from an autogenous vaccine than can be expected from a stock one. The proof of this statement is that in every instance where a vaccine was used in the treatment, the presence of the antibody could be proven by the complement fixation test. How soon these antibodies appear I am not in a position to state at the present time, but hope to be able to render some report during this session, as I am carrying out an investigation along these lines at present. Another question to be answered is how long these antibodies remain after treatment is discontinued.

The question of mixed injection must not be overlooked in the use of vaccines and it has been my rule during the past year in the making of autogenous vaccines not to isolate the special organism, but to grow all bacteria present synergistically and to standardize this vaccine by the predominat-

	Case	Civil State	Duration	Uterine Discharge	Gonococci	Reactions	Menstrual Show	No. of Injections	Length of Treatment	Result
1	I. C.	Single	10 months	Present	Present	Temp. 101	Present	Seven (50 and 75 million)	9-20/07 to 11-3/07	11/4/08 No recurrence

Cases Nos. 1-2-5-6-7-10-20-21-22 had specific bladder infections.
Cases Nos. 3-10-14-21-23 occurred as associated with acute specific infection of vaginal and cervix.
Case No. 5 had at the same time gonorrheal involvement of left ankle.
In Cases Nos. 16-20-23 one tube and ovary had been removed at previous operation.
Case No. 7 had a double cervix.
Case No. 18 was complicated by vulvovaginal abscess.

ing organism. This sort of vaccine has given me the best results.

In the treatment of these cases I employed all the medicinal, hydrotherapeutic and mechanical procedures used in these conditions. As a rule I clean the alimentary tract with a saline and then administer opiates. The benefit from them is twofold: they not only lessen the pain and thereby restlessness and exhaustion, but they lessen or suspend the vermicular movement of the intestines and allow nature to do her best in regard to limiting the injection.

The head of the bed is elevated at least 12 inches and hot counterirritants and hydroscopics are applied to the lower abdomen. After the severity of the acuteness has passed I order a hot iodine vaginal douche twice a day. I like urotropin and as a rule use large doses. Food and water are restricted until the pain and tenderness are greatly reduced or absent.

As to the specific treatment, we have two agents at hand, serum and vaccine. It is inexplainable to me how men who exercise most excellent judgment in the use of serums, say for instance in the treatment of diphtheria, will use it so impractically in gonorrheal conditions. The gonococcic serum contains specific antibodies, and when used should be used for effect. Use it like diphtheric serum: push it for effect. Who would think of giving 500 units of diphtheric antitoxin every four to seven days in a severe case of diphtheria, and still that is what is done with gonococcic antitoxin, and then the users say it is worthless because they get no results.

Give 2 or 4 c.c. at the initial injection; if no benefit has been derived in three or four hours double the dose, and double again three or four hours later if satisfactory results have not been obtained. I have given as high as 16 c.c. within twenty-four hours and have never seen any unpleasant results other than a slight erythema or severe attacks of "hives." I have seen less of this since using the horse instead of the sheep serum and it seems to be equally efficient.

The benefit to be derived from the serum must come in the first twelve or thirty-six hours after its injection. These long, drawn-out, small injections of serum are a waste of time and money. As a rule I give with the initial injections of serum a moderate dose of mixed gonococcic vaccine.

The microscopical and cultural study of these as well as other infectious conditions show that we rarely, if ever, have a one-germ disease. The sooner a polyvalent antigonococcic serum is made the sooner will the treatment of these conditions be more satisfactory. As soon as it is possible I make an autogenous vaccine for use at subsequent treatments.

This line of treatment has invariably in my hands, within twenty-six or forty-eight hours, made an entirely different clinical picture than one would expect to find. The patient is comfortable, temperature and pulse are within proper limits, local tenderness and rigidity are reduced to the minimum. The facial expression is happy and a desire for food is one of the first expressed.

But keep them in bed for ten days and as quiet as possible. Under no circumstances must there be a sudden or strenuous movement of any part of the body. This is a measure hard to enforce, but a great deal depends on it, for I have seen in several instances a classical recurrence when these orders were disobeyed.

The vaccine should be repeated every seventh day for at least five doses. This is an outline of the treatment I use in the acute conditions.

When you see these cases in the interval between attacks, of course the management is somewhat different. Iodine douches, urotropin internally, and quiet are recommended. Here in nearly every instance an autogenous vaccine is prepared for the initial injection. Following this injection from six to twenty-four hours the reaction begins. In some instances the first reaction is severe. Pain, almost of the intensity of past attacks, is present, the temperature and pulse go up and the patient is very uncomfortable. In cases where there is uterine

or cervical involvement also, it is common to have a profuse bloody discharge during this reaction.

The reaction should not extend over twenty-four to thirty-six hours at the utmost unless the vaccine dosage has been too large. If a continued reaction is produced either break it with a small dose of vaccine or lengthen the interval before the next injection and reduce the dose. As the reaction passes off the subjective symptoms disappear and the patient experiences less inconvenience than before the injection. As a rule I keep these cases quiet two days after the reaction has passed. Subsequent reactions as a rule are not severe, but patient should be kept quiet for twenty-four or thirty-six hours.

The size of the dose depends altogether on the extent and virulence of the infection and the weight and physical condition of the patient.

I continue the injections every seven days until objective and subjective symptoms have disappeared, and then as a rule give two more injections.

The results obtained in the twenty-five cases have fulfilled every expectation. Some of these cases were discharged four years ago and none of them has returned for treatment; some I have seen since and have learned that they have given birth to healthy children and that the pregnancy and labor was normal.

On examination in some instances little or no induration is found in or around the tube; in others where the condition when first seen had been present for a long time and large masses were present either on one or both sides some induration remains. The question of adhesions and consequent constipation and obstipation has not been lost sight of. The evidence is to the effect that there is a great deal less of this in the cases treated along these lines than after the operative procedures.

I wish to hereby express my appreciation and acknowledge the valuable assistance rendered me by the cooperation and suggestions of several surgeons and therapeutists in this work.

The Atherton.

FRACTURE AND DISLOCATION OF THE UPPER END OF THE HUMERUS.*

By JOSEPH B. BISSELL, M. D.,

NEW YORK.

VISITING SURGEON TO ST. VINCENT'S AND BELLEVUE HOSPITALS.

Fractures about a joint, when in the long bones, and close to the joint surface, are always interesting. When complicated with a dislocation they are still more so. The difficulty of recognizing this condition is great, and the perplexities of treating it when recognized even greater. Many troublesome symptoms following an unsatisfactory reduction of a dislocated shoulder may be explained by this condition of fracture-dislocation. The immediate and ultimate results arising from such an injury are always problematical, and a positive diagnosis more or less unsafe. Particularly is all this true in fractures and dislocations of the humerus at the shoulder joint. This combination injury, while not a common one, is more frequently seen now than formerly. The increase is due to our greater facility in the use of the modern means for clearing up the diagnosis, notably by the fluoroscope or radiograph. The *x*-ray also explains why pain, spasm, and return of the deformity are present in many instances after the apparent reduction. Anesthesia is of great help, both in diagnosis and treatment. Crepitus may not be found even under the anesthesia, but the *x*-ray demonstrates the fracture almost invariably. The importance of attaining a definite knowledge of the local condition in these injuries is obvious. With all our knowledge and facilities for treatment of this condition it is still difficult enough at times to reduce the deformity and to secure a proper apposition and immobilization of the fragments. The etiology of this accident is instructive. The trauma which produces dislocation of the shoulder joint is not usually a severe one. The injury producing fracture about the neck of the humerus may or may not be caused by great force. It would seem that, however strenuous the exciting cause may be, after it had dislocated the shoulder it could hardly go on and fracture the bone, or vice versa. Again, if the head of the bone is broken off first, close to the upper extremity, as occurs most frequently in these cases, how is it possible for there to remain leverage enough to dislocate the joint surfaces? From the study of a number of these fracture dislocations I have evolved a theory as to the probable causation. The theory is not exactly creditable to the medical profession, but I am sure it is quite often true. One will notice in the history of most of the cases which are included in this short paper the patient asserts that the injury which produced the dislocation was not a very severe one. One will also notice that in almost every case the patient reports that vigorous, long continued, and very forcible efforts were made to reduce the dislocation before the patient came under our observation. Also in some of the cases it was insisted that the bone was heard to return to the socket, but the symptoms of dislocation, in spite of that, remained unrelieved. My theory is, and it seems a fair and logical inference from these statements, that the bone was fractured by the force used in trying to reduce the dislocation. The noise which the patient and the doctor heard, and the "slipping into the joint" which the physician feels, was nothing of the kind, but was due to fracture produced in this manner. The following cases are typical of some of the phases of the condition just described:

Case I.—Miss G. School teacher. Aged 40. Slipped and fell on the icy pavement in January, 1906. She was unable to get up on account of the pain in her right shoulder and the distortion of her arm and forearm. She was assisted to her home by bystanders, and her physician sent for. She had a typical deformity with sub-clavicular displacement of the head of the humerus. Her physician and two other doctors made repeated, vigorous and strenuous efforts to reduce this dislocation by every method known to them, including the knee and heel in the axilla, with strong leverage against such fulcrum. Apparently they felt the bone go into the socket, but on examination the symptoms of deformity remained the same and the pain was much greater. Finally, patient and doctors being thoroughly exhausted, and the result unsatisfactory, after several hours' work, the patient was advised to go to a hospital for treatment. There, under *x*-ray examination, a subglenoid dislocation of the head of the humerus, with an almost transverse fracture, was clearly defined. After remaining in the hospital several days open operation was performed and the head of the bone, with much difficulty, was returned to the glenoid cavity. It was

*Read before the City Hospital Alumni December 20, 1911.

then found that the fractured surfaces were held together very easily in good position by external splints. The wound healed without reaction, and the patient made an uneventful recovery. She left the hospital at the end of six weeks with normal function of the joint.

Case II.—Frank H. 35 years old. House painter. While at his work on May 1, 1907, fell from his ladder a distance of about twelve feet, striking on his right shoulder. He suffered great pain at the joint, the arm was held abducted with the elbow sticking out from his side. Fullness in the axilla and concavity under the acromial process completed the typical symptoms of a subglenoid dislocation. He was taken to his home in the country and for several days repeated attempts were made to reduce his deformity. After final vigorous leverage efforts the bone was eventually manipulated and pushed into its socket. After the reduction the deformity seemed corrected, normal fullness returned to the point of the shoulder and disappeared from the axilla, but pain remained and was very severe, while the function of the joint was not restored. At the end of ten days, the man remaining in constant pain, and the shoulder joint so tender it could hardly be touched, the patient was brought to New York for a consultation. The *x*-ray at once cleared up the situation. The head of the humerus had been restored to the glenoid cavity, but the articulating surface was turned away from the glenoid fossa, and looked upwards, outwards and forwards. The greater tuberosity was resting in the concavity of the articulating surface of the scapula. A section of about one-third of the head of the humerus, including a portion of the articulating surface and part of the lesser tuberosity, had been broken away from the bone, torn off, evidently, by the contraction of the subscapular muscle. The patient was sent to the hospital, and under operation this fragment of bone was removed, and the articular surfaces restored to as nearly their normal positions as possible. The wound was closed with a small drain. Following a slight process of infection in the soft tissues, recovery was quite rapid, leaving a joint only slightly impaired in its function.

Case III.—Mrs. W. Housewife. Aged 42. In March, 1907, was dragged some distance after falling from a trolley car, and among her other injuries was a dislocation of the right shoulder. There was a subclavicular deformity, but no evidence of fracture at the time of the first examination. Repeated attempts at reduction failed, although it was thought by the physicians manipulating the bone that they had felt it slip into place. After these efforts it was thought that crepitus could be felt, and the patient came under my care for an opinion. Examination showed a typical subglenoid deformity with distinct point of crepitus. *X*-ray examination discovered the head of the bone below the glenoid fossa, and the external tuberosity, together with a part of the articular surface of the head, fractured off. There was an irregular line of fracture running diagonally down the bicipital groove to the internal surface of the humerus, but not extending quite though it. Through an open operation the portion of the bone separated from the shaft was removed and the articular surfaces of the joint restored to their normal relations. Before removing this fragment an endeavor was made to replace it, hoping thus to conserve the function of the large muscles attached to the greater tuberosity. Repeated efforts, however, failed to return it to its normal position, and it was found also impossible to return the head of the humerus to the glenoid fossa without removing this large piece of bone. As far as it was possible to do so the periosteal insertions of the muscles attached to the greater tuberosity were preserved. After taking away the loose piece of bone it was comparatively easy to place the articulating surfaces together. In spite of a slight infection the wound healed within a short time, and the patient at this date has perfect function of her joint. This is rather remarkable considering the disturbances to the muscular insertions and to the groove of the bicipital tendon arising from the osseous injury.

Case IV.—Mr. J. R. 55 years old. Clerk and messenger. Had a history of epilepsy and periodical alcoholism. Had dislocated his shoulder twice before this occasion. January 12, 1909, fell in an epileptic fit while drunk. Was taken to the hospital and the next morning an attempt was made to reduce a subclavicular dislocation of the left shoulder. This was unsuccessful, and under anesthesia repeated attempts were made, also unsuccessful. Following this, after several days' rest, a fluoroscopic examination showed the head of the humerus out of the glenoid fossa and resting high up under the clavicle. There was also a long crack extending from just below the greater tuberosity downward and inward transversely across the bone. This fracture appeared to be about four and a half inches in extent. The fragments seemed to remain in good apposition to each other except when manipulated in the endeavor to replace the head of the bone in its normal position. As the patient had a long history of alcoholism, some arteriosclerosis, and the urine showed numerous hyaline and granular casts, together with the fact that it was easy to adjust and hold the fragments in good position, it was decided to try and heal the fracture before making any attempt to reduce the dislocation. The arm was therefore put up with a shoulder cap and a triangular splint in the axilla, which appeared to hold the fracture firmly and satisfactorily. At the end of six weeks bony union had taken place and an endeavor was made to reduce the dislocation. This failed, as did further efforts, rather than run the risk of refracturing, and also because of the history of three dislocations already, I decided to leave the bone in the situation where it was and let him have a false joint in this position. Owing to changes in the joint relations and structure it seemed quite likely that if reduced the dislocation would be inclined to recur. The man has been under observation ever since and has now a very satisfactory result. There is very little restriction of the function of the joint and it does not interfere at all with his occupation.

Case V.—Mr. B. H. 65 years old. Merchant. February 10, 1908. Slipped and fell on the ice in walking up a hill in the village in which he lived. He suffered a subglenoid dislocation of his left shoulder which two doctors tried several hours to reduce. This was on the night when he was hurt, and the result was unsuccessful. The next morning they gave him ether, and with another physician tried again. They felt the bone go back, but it would not stay in place, and at this time they discovered what they took to be the head of the bone posteriorly and low down in the axilla. The patient was suffering a great deal of pain and it was decided to send him from the little village in New

Jersey in which he lived to New York. I saw him the second day after the injury and felt what I thought to be the fractured head of the humerus separated from the shaft in the lower part of the axillary space lying close to the chest wall in the anterior surface of the latissimus dorsi muscle. The *x*-ray plate shows the humerus fractured through the anatomical neck, the upper end of the lower fragment resting upon the inferior edge of the glenoid fossa. Posterior to this, and almost under the skin of the posterior axillary wall, is seen the upper fragment. This consists of the head of the bone and is loose and easily movable in this location. The day following I cut down from behind, removed the fragment, and closed the wound primarily. At the end of six days he went back to the country with his arm in a sling. The wound healed *per primam*, and he had apparently a normal shoulder joint. He has been seen within the past few weeks, and the functions of this joint are entirely satisfactory.

Case VI.—Miss N. Trained nurse. Was injured in April, 1908, slipping and falling, striking on her shoulder. She is a very fleshy person about 42 years of age. The injury took place two days before I saw her. She brought with her an *x*-ray plate showing dislocation and fracture of her left humerus. The head of the humerus was well forward under the clavicle where it was easily felt by examination, crepitus could not be detected by manipulation, but in the plate a fracture running from internal side of the anatomical neck downward and outward to the external surface of the humerus is plainly seen. She complained of great pain on the slightest motion of her shoulder joint. The patient states that diagnosis of dislocation had been made soon after the injury, and that several efforts had been made to reduce it. Treatment consisted of anterior arthrotomy, reduction of the dislocation, which was very difficult, adjustment of the two fractured surfaces together, which was very easy, and retaining them in position by means of two wire sutures. Apposition, after it was accomplished, was perfect. This patient made an uneventful recovery, and in the course of six weeks, aside from a rather long and unsightly scar, her condition was entirely satisfactory.

Case VII.—Rebecca H. December 10, 1909. Worker in a waist factory. This patient was injured in a struggle to escape from a fire in the building in which she worked. Several of her coworkers were injured or killed at this time and great force and strenuous efforts were made in getting her out of the mass of struggling, frightened people. It was difficult to say exactly what kind of an injury caused her condition. At the hospital, on the day following her admission, an *x*-ray examination showed dislocation of the shoulder posteriorly, and fracture just below the anatomical neck of the humerus. Open operation, reduction of the dislocation, and readjustment of the fractured surfaces were rather easily performed by means of a posterior and anterior opening. The fragments were retained in very good position by external splints, and when the patient left the hospital, aside from a little stiffness, she had good joint function.

Case VIII.—Sarah R. 56 years old. February 8, 1910. Patient, while cleaning a window, lost her balance and fell a distance of one story. She was brought to the hospital complaining of pain in her shoulder and inability to use her right arm. On examination the characteristic deformity of dislocated shoulder was seen, and the head of the humerus could be felt under the clavicle. Several attempts were made to reduce the bone without anesthetic. Next day the patient was taken to the operating room and under chloroform reduction was made. After recovering from the anesthesia, pain and inability to use the arm continued, and the appearance of the shoulder was not characteristically normal. The result was not satisfactory to either patient or surgeon. She left the hospital ten days after entering, still complaining of pain and inability to use the arm. At another hospital, a few days later, the *x*-ray plate showed the head of the bone on the lower edge of the glenoid fossa, and fractured off from the shaft just below the anatomical neck. Also there could be seen an apparent fracture of the neck of the scapula. The patient refused operation and was lost sight of, so that the ultimate result is unknown.

Case IX.—A. C. Aged 39. Carpenter. March, 1910. Fell down a few steps and injured his right shoulder. He was brought to the hospital and a diagnosis of dislocated shoulder made by palpation and manipulation. Several efforts to reduce the dislocation were made unsuccessfully. The *x*-ray examination showed a transverse fracture of the humerus below the tuberosity, dislocation of the head below the glenoid fossa; there was great mobility and wide separation of the fragments of the humerus. An open operation was performed, and on account of the movability of the fragments two Lane plates were used to restore and retain the continuity of the bone. Union took place by first intention. The man had an uneventful convalescence until the eighth day, when he developed an alcoholic pneumonia, from which he died.

The treatment of these cases depends wholly upon our appreciation of the pathological condition. It it sometimes impossible to make an anatomical reduction by manual methods or by ordinary external appliances or in this class of injuries without opening the soft tissues down to the joint or to the fracture. If this is not done it very difficult to put and retain the fracture in good position. *X*-ray examination should always be used to confirm the reduction and reposition of the fragments. External mechanical devices to retain in proper position the fragments in a fracture close to the shoulder joint, however ingenious, usually result in failure, as does also the endeavor to first reduce the head of the bone to its correct position before endeavoring to reduce the fracture. The reason for this inability to hold the fragments in apposition is of course the shortness of the upper fragment and the impossibility of getting it within the grasp of our mechanical devices. Restoration of the head of the humerus to its normal position in the glenoid cavity is often impossible, even under anesthesia, because of the shortness of the upper fragment. This fragment may consist only of the head of the humerus alone, sometimes only of a section of it. The recognition of these facts leads the surgeon to consider the more radical but more definite and certain procedure of open operation.

It is a great satisfaction when the indications point as plainly as they often do in these cases to operative measures. Once having recognized the impracticability of restoring the injured parts to their proper position and function by manipulation there is nothing else for the surgeon to do except cut down upon the site of the injury, and properly

and consistently adjust the distorted tissues to as nearly as possible their normal state. Operation naturally resolves itself into one of two methods of procedure. Either we endeavor to unite the fragments and keep them united until union takes place or we may be compelled to remove the upper fragment entirely. Here we use the lower fragment in the new joint. This latter variety of treatment is forced upon us by any of the following conditions, the impossibility of proper adjustment of the two fragments to each other, comminution of the fragments, too wide displacement of the upper one, complete destruction of the circulation and nutrition of the upper fragment, smallness of the upper fragment, or destruction of the joint surface of the glenoid cavity. It is curious to see what good joint function may be had in the shoulder joint, in spite of the fact that the head of the bone has either been removed entirely from the joint surface and the human body, or that a false joint has been formed with a shortened or lengthened humerus, as the case may be. In such cases satisfactory shoulder joints are not infrequent with the glenoid cavity entirely out of business. The false joint in such cases not infrequently results in an almost normally acting shoulder, even with the glenoid fossa completely deprived of its function. To restore the fractured humerus and retain it in its continuity till bony union occurs, there is no device to be compared with the steel plate of Mr. Lane. Collars, rings, wiring, interbone supports of various kinds have not in practice worked out as well as this simple device. Immobilization is necessary for proper and rapid repair of the bone. This can be obtained in the simplest and most efficient manner by a single or double Lane plate. When two are used they are not united, but applied at a considerable distance from each other, if possible on opposite sides of the bone. In these high fractures of the shaft of a long bone a single plate allows of too much motion between the fragments to obtain the firm apposition necessary. When the upper fragment is too short to allow of the adjustment of a Lane plate, and if in the opinion of the surgeon it is impossible to hold the fragments in good position, the upper fragment is to be removed. If one wishes to be overcareful or the lower fragment tapers into a sharp spicula of bone, this may be smoothed or cut off with a bone forceps or Gigli saw. The arthrotomy itself is not a dangerous operation, though likely to be difficult and at times tedious. Mr. Lane attaches great importance to the asepsis. He says that the asepsis required in abdominal work is not to be compared with the necessity for care and cleanliness demanded in plating fractures. The plate may be removed at any time by a slight operation if it should subsequently be thought desirable.

The experience of the writer with these cases brings out three points for consideration.

1st. That in a fracture-dislocation at the shoulder joint the fracture is usually secondary to the dislocation, and is caused by ill-advised and unskillful efforts to reduce it.

2nd. The immunity with which the shoulder joint may be operated upon under proper conditions and for proper purposes.

3rd. The remarkable ability of the shoulder joint to adjust itself to a great amount of damage and injury and to eventually recover its functions, or to more or less successfully replace them.

46 West Fifty-fifth Street.

SALVARSAN AS A CURE OF SYPHILIS.*

A RÉSUMÉ OF RESULTS OBTAINED IN CASES AFTER TEN MONTHS' OBSERVATION.

By JAMES M. WINFIELD, M. D.,

BROOKLYN, N. Y.

The rapidity with which articles upon salvarsan have appeared in medical literature testifies to the continued interest in the subject. As it would be useless to attempt to collate the observations of various authors and present them as a paper, I have accepted the suggestion of our president and will offer for your consideration an analytical résume of the results obtained in a hundred cases of syphilis treated with the new drug that have been under my observation for ten or more months.

Until recently it has been impossible for anyone to write much about the lasting after-effects because there had not been sufficient time for observers to draw conclusions. It is an undoubted fact that much harm was done by some of the premature enthusiastic reports that were published within a few months after Ehrlich announced his discovery, for there are those who still think that salvarsan is a specific for syphilis, and that a single dose of a few decigrams will effectually and thoroughly free the system from the syphilitic virus.

The cases that furnished the notes for this paper were both hospital and private patients. For obvious reasons it will not be necessary to give the detailed history of each case. I will limit the paper to the general analysis of the hundred cases, making special comment upon any important phase or symptom observed during the ten months the patients were under my care.

Eighteen of these cases were females and eighty-two were males; the drug was administered by the four recognized methods, viz., subcutaneously, intramuscularly, intravenously, and by the subcutaneous or intramuscular injection of the oil suspension. The subcutaneous method was used only seven times; in three cases the drug was given in suspension; in the remaining four the clear alkaline solution was employed. Two of the patients in whom the suspension was used developed necrosis of the tissues surrounding the point of injection; the third developed an abscess. Two in whom the clear alkaline solution was used subcutaneously also had necrosis and abscesses as a complication. One of these cases is of especial interest on account of the tardy development of the necrosis. The patient was a young woman in the early secondary stage of the disease. Twenty cubic centimeters of the clear solution were injected deep into the tissues between the shoulders; a few days later the injected area became inflamed and indurated, but these conditions disappeared under massage. Two months later the patient re-entered the hospital complaining of pain and tenderness between the shoulders. Upon inspection it was found that there had developed a large necrotic area, which was removed surgically. The patient went on to an uninterrupted recovery. The Wassermann reaction was at no time negative. (Since this paper was read the patient has again entered the hospital suffering from the late secondary manifestations of syphilis, eleven months after receiving salvarsan.) This case emphasizes the fact that salvarsan has absolutely no effect when the injection is followed by induration, because under this condition the drug is not absorbed.

*Read before the Brooklyn Pathological Society, October, 1911.

Most of the cases received the drug by the intramuscular method, and neither necrosis nor abscesses developed in any of them; a long needle was used and the solution was injected deep into the muscle of both buttocks. Many of the earlier cases complained of considerable pain and in some there was a slight induration lasting a few days. It would seem that the reason why the early cases suffered so much more pain than the later ones was that the needle employed was too short and that the quantity of the solution was too large; it has been found that with the salvarsan now on the market it is possible to obtain a proper solution with considerably less water, so that instead of being obliged to inject twenty or more cubic centimeters, many times one can get a satisfactory solution with only twelve to sixteen cubic centimeters. Another cause of pain when the drug is introduced intragluteally is that the injections are made too low in the buttock. When the needle penetrates the lower border of the gluteus maximus muscle some of the solution is apt to work down into the fascia and tissue underneath and cause a certain amount of inflammation and induration. If the induration is at all pronounced the sciatic nerve may become involved in the inflammatory process, causing severe neuralgia and, as in two of my cases, loss of muscular function. Experience has taught that if the salvarsan solution is properly prepared and correctly placed in the gluteal muscle the pain in many instances is only a little more severe than an ordinary injection of salicylate of mercury.

The intravenous method was employed in a number of cases, mostly in private patients. Judging from the articles dealing with this method one would think it is a very simple matter to always place the needle in the vein at the first attempt; but this is not the case, for it often happens that even when the vein is large and prominent the moment the needle strikes the outer wall of the vein the vessel slips aside. Instead of penetrating it and becoming continuous with the tube of the vein, the needle either desects up the walls of the vessel or goes clear through it. In adipose people and in most women the quickest and most satisfactory way is to cut down upon the vein and then introduce the needle. I have come to the conclusion that the simple gravity apparatus is much better for general use than any of the more complicated ones that are recommended.

In discussing the comparative advantages of the different methods of administering the drug, my experience coincides with that of other observers that the subcutaneous method should never be used, because the solution comes in contact with the subcutaneous fat, and it has been demonstrated that the minutest quantity of salvarsan injected under the skin causes inflammation and necrosis of the fatty tissues, and is thereby rendered inert, for the same reason the oily emulsion should never be placed subcutaneously. The intramuscular method can be utilized for the general run of cases, especially if the patient can be kept quiet for at least five days; indeed all patients receiving salvarsan should be kept quiet and under observation for at that length of time. The intravenous method is the ideal one, especially when the patient is obliged to pass from observation shortly after the operation, or when, for any reason, the disease must be gotten under quick control. It is undoubtedly the best method in all acute or obstinate cases, for in them time is precious and the quicker we get the patient under the influence of antisyphilitic remedies the better. As far as rapid results are concerned there is but little gained by giving the drug intravenously when the patient is in the tertiary stage of the disease or even after the secondaries have subsided, unless, of course, the case is one of malignant syphilis. In fact, the symptomatic cure of the tertiary lesions is as rapid and more permanent when the drug is injected into the muscles, probably because of the slower absorption of the remedy. Experience has taught that it is not safe to give salvarsan by any method to ambulatory patients. It is in this class that the oily emulsion can be employed. I have used this emulsion in eight cases and I think the symptomatic cure has been much slower than when the solution has been used. In all but one the Wassermann reaction never became negative, and five of the cases rapidly developed recurrent syphilitic symptoms. Perhaps in these cases the absorption of the drug was too slow, and on account of this the treponema became immunized to the toxic effect of the drug.

The behavior of the Wassermann reaction in my cases was similar to that reported by others. In four the reaction never became negative, in two of these the drug was administered subcutaneously and one of them developed an extensive necrosis. In the remaining cases the Wassermann became negative in from ten days to six weeks. The earliest of these was in a young man aged nineteen with a chancre of the lip and tongue and a beginning secondary eruption. The *Treponema pallidum* in large numbers was demonstrated in the chancres the day before salvarsan was administered. A serological test made at the same time was strongly positive. Twenty-four hours after the drug had been given the labial chancre showed signs of improvement and the one on the tongue was practically healed. None of the specific microorganisms could be found in the secretions from the chancre on the lip, the swelling in the glands under the jaw had begun to subside, and the eruption was nearly gone. The Wassermann reaction was delayed upon the eighth day and negative upon the tenth, and has remained so ever since. This is evidently an instance of a cure after one dose of salvarsan. One year has elapsed since the patient received the salvarsan and he is both serologically and clinically free from any symptoms of syphilis. In 60 per cent. of the cases the Wassermann reaction became negative in about four weeks; in 10 per cent., between the third and fourth week; and in the remaining 30 per cent. the negative reaction did not occur until after the fifth week. Out of the hundred tabulated cases there are forty-five that still give a negative reaction after six months.

To thoroughly test the value of salvarsan, up to this time none of the patients in this series has had any other antisyphilitic treatment. Since this paper was read some of the patients have received a second dose of salvarsan and all have been put upon mercury. Of the four cases that never became negative two developed late secondary symptoms of syphilis, one two months and the other four months after receiving the salvarsan. The other two patients have not had any clinical manifestations of the disease. Both were in the tertiary stage. One was a man who had not been free from some syphilitic cutaneous lesion for six years. After receiving the salvarsan his tertiary ulcers and new growths healed, softened, and disappeared. This was the first case of the series to receive the

drug, which was administered in a dose of only four decigrams deep in the muscles between the shoulders. Aside from some slight discomfort immediately following the injection, the patient never experienced any special pain, the tertiary lesions being all well within a month and remaining so for a year. Monthly serological tests have been made and at no time has the reaction been negative; in fact, most of the time it has been strongly positive. Seventy-one of the cases have not yet shown any clinical evidences of the disease.

Among these reported cases there were six cases of nerve syphilis: Epilepsy, tabes and spastic spinal paraplegia. Two of the last showed some improvement. In one patient, a female in the incipient stages of tabes, the symptoms were ameliorated and the disease was apparently arrested. The case of syphilitic epilepsy showed immediate and marked signs of improvement. The tertiary cutaneous lesions healed, and after one severe convulsion occurring shortly after the drug was administered, all the symptoms of epilepsy ceased and the Wassermann reaction became negative in three weeks. Nearly three months later she suddenly became maniacal and was removed to the Kings Park Hospital for the Insane; a Wassermann taken there gave a positive reaction; she is still at the State Hospital, her mental condition is considerably better than on her admission, and a late report states that she has not had any more epileptic convulsions.

Unless the involvement of the nervous system is of recent origin it is unwise and even risky to use salvarsan; every observer from Ehrlich down has warned against this. Salvarsan does not possess the power of restoring lost tissues; all it is supposed to do is to kill the luetic organism and in a certain measure to sterilize the system of the specific poison, but it cannot restore lost cerebral tissue any more than it can produce an imperceptible scar over the site of a chronic ulcerating cutaneous syphilide. Much has been written both pro and con regarding the effect of salvarsan upon the optic and auditory nerves; only three of my one hundred cases have shown any disturbance of hearing and this has been only a slight tinnitus. The drug was used in three cases of secondaries complicated with acute iritis, and the curative effect upon the eye symptoms was as wonderful as in the cases with cutaneous lesions. The case of double optic neuritis that I reported in a paper read before the Medical Society of the State of New York, April, 1911, has progressed until, at the present time, the patient is totally blind. His Wassermann reaction has been positive for over three months and he refuses further treatment. At first I feared that this eye symptom was due to the toxic effects of salvarsan upon the optic nerve, but recently I have learned that the patient has been in the habit of drinking "white whisky," a compound of methyl alcohol and aromatics, and I am now inclined to believe that this explains the occurrence of the eye complications in this case better than either the toxic action of the salvarsan or the degenerating changes of syphilis.

I think that any one who has had experience with this new drug is justified in sounding a word of warning against the indiscriminate use of salvarsan. This drug is not indicated in all cases of syphilis, or is our experience with it great enough to warrant its use in routine office work. There is considerable risk in giving this drug to office or dispensary patients, for serious accidents have happened even when every care and precaution had been taken and the patients had been surrounded by every hospital facility.

Until time has proved all the possibilities for good or bad that salvarsan possesses, it would be far better if all would agree to administer it only by means of the intravenous method, thereby avoiding all possibility of malpractice suits or the temptation on the part of the operator to report or promise anything that might not prove to be absolutely true.

From the study of these cases it may be concluded that although salvarsan is a powerful antisyphilitic, it does not cure the disease any more surely than does mercury, but it does relieve the clinical symptoms more quickly than any other known remedy. Therefore it should always be given when for any reason there is need for haste. One or more doses of salvarsan cannot insure a cure, and each patient should be put upon a course of mercury within three months after receiving the new remedy. Experience indicates that if syphilitic patients are so treated the possibilities are that the duration of treatment can be reduced to one-half of the time it formerly took to effect an apparent cure. The introduction of salvarsan has done much to emphasize the value of the Wassermann and other serological tests. All cases under antisyphilitic treatment should be subjected to these tests, for in many instances this is the only way one can gauge the effects of the remedy. One should always have in mind the possible occurrence of untoward by-effects; all of the precautions known to the modern scientific physician should be observed for the protection both of the physician and the patient. Salvarsan is practically useless in parasyphilitic nerve diseases unless it is given when the disease first manifests itself. The intravenous method of administration is the one of choice, especially when a prompt effect is desired. If it were not for the pain and discomfort, the symptomatic effect would be as sure when the drug is administered intramuscularly. The divided doses of the oily emulsion provides the only really safe method for office or dispensary administration.

CLINICAL TECHNIQUE FOR ENZYMES.

By FELIX VON OEFFLE, M.D.,

NEW YORK

All body liquids contain more or less enzymes and for the statement of health or sickness, it is very important to be able to estimate the amount of enzymes in comparison with the normal. The enzymes can be divided into five different groups: (1) Reductases, (2) oxydases (oxygenases and peroxydases), (3) albumin-splitting enzymes, (4) carbohydrate-splitting enzymes, (5) fat-splitting enzymes.

The reductases are not very important and, therefore, can be excluded in the clinical tests. For the four others we will give simple clinical tests.

The first thing to do is to get the enzymes concentrated and purified and without coloring matter. This is possible by the fact that enzymes are soluble in glycerol water and insoluble in alcohol without deteriorating them, if we work quickly enough.

Any material, dry or liquid, can be mixed with nine times its weight of 10 per cent. glycerol water. This is then centrifuged and the almost clear supernatant liquid now contains the original enzymes

ten times diluted. Now 50 c.c. of this liquid (equal 5 grams material) is mixed with 50 c.c. alcohol; the mixture is allowed to stand for five to ten minutes, and then centrifuged. We pour the supernatant liquid off and wash the sediment again with 40 to 50 per cent. alcohol, and centrifuge again. The sediment now contains the enzymes of 5 grams original matter.

The liquid is poured off carefully and the sediment again dissolved in 10 per cent. glycerol water. If the solution is 5 c.c., the concentration of the enzymes is the original concentration. If we get 10 c.c. solution, it is only 50 per cent. of the original concentration, etc. The value of the foregoing is that we have less of foreign matter than in the original material, and especially not so many pigments as in feces.

Oxydases Test.—Make a fresh solution of 0.5 per cent. metadiaminophenylene. Pour 5 c.c. in each test-tube and put them in an incubator with a temperature between 50° C. and 55° C. for about one-half hour. (If the temperature of the incubator is below 50° C. these tests are not so conclusive, and if it is above 55° C., it will be impossible to perform these tests properly.) After the tubes have been in the incubator the solution must be of the correct temperature and of a violet color. Now drop by drop add the enzyme extract received as above described. If oxydases are present the violet color turns gradually to brown. (If reductases are present, the violet may become more bright.) The oxydases can be divided into two groups, called oxygenases and peroxydases. The foregoing test is used for both; but the last one needs the addition of peroxide to react. The amount of extract used to get an exact color stays in an inverted relation to the amount of oxydases present.

Albumin-splitting Enzyme.—Make the following solution, which should be made fresh each day: 0.5 gram casein is mixed with 50 c.c. water and 5 drops hydrochloric acid. This is shaken up very well and the supernatant liquid decanted and thrown away. This purification is absolutely necessary because the purest caseins of the market contain albumoses and peptones, the presence of which will interfere with this test. To the remaining undissolved casein is added 1.0 gram Na_2CO_3, and 10 c.c. Fehling's copper solution, and 5 to 10 c.c. Fehling's alkaline solution, and the whole brought up to 1 liter with distilled water. Place 5 c.c. in each test-tube, put in incubator for about one-half hour. This should come out of incubator a very light blue color. Now drop by drop the enzyme extract is added until the color changes to violet, then pink, and finally disappears. One will get all these colors if a casein-splitting enzyme is present. The amount of enzyme is higher in inverse relation to the amount of extract used.

Carbohydrate-splitting Enzyme.—Take 5 grams of Kahlbaum's soluble starch, add about 100 c.c. distilled water, heat, stirring and shaking until there is a clear colorless solution. Then add distilled water to bring up to 1 liter. Drop by drop add a weak solution of iodine in potassium iodide (Lugol's solution) until the whole solution becomes a blue color. Pour 5 c.c. into each test-tube and put in the incubator for one-half hour. Then drop by drop add the enzyme extract. If a starch-splitting enzyme is present the color turns to violet, then pink, and finally disappears. The amount of enzyme is higher in an inverse relation to the amount of extract used.

Fat-splitting Enzyme.—Make a fresh solution of 1 per cent. Na_2CO_3, add few drops phenolphthalein solution. Then mix equal parts of the above solution either with melted butter or cotton-seed oil or olive oil. Butter is more sensitive than other fats. Shake very well, and if it does not become red, titrate it with NaOH solution until it becomes strongly red. Now place 5 c.c. in each test-tube and put in incubator for one-half hour. It will be two-stratified when removed from incubator. It must again be shaken until it becomes a homogeneous emulsion. Drop by drop the extract is added. The red color becomes paler and paler, and finally yellow if a fat-splitting enzyme is present. The amount of enzyme is higher in relation to the amount of extract used.

These tests are especially good for stomach contents containing regurgitated intestinal contents, or for duodenal contents, and also for feces. With matter of this kind other tests are difficult by reason of the color impurities.

326 East Fifty-eighth Street.

Hypophysis Medication in Obstetrics.—J. Parisot and A. Spire employed the extract of the entire hypophysis in ten cases of pregnant or puerperal women, with some success in causing increased uterine contraction. The extracts of the entire hypophysis or of the posterior portion of the gland have been used in cardiovascular and renal cases as a means of stimulating unstriped muscle.—*Annales de Gynécologie et d'Obstetrique.*

Serotherapy of Pertussis.—R. Duthoit has been experimenting with a serum prepared at the Pasteur Institute of Brussels for the treatment of whooping-cough. He has as yet treated but twenty cases but the results have been encouraging. The serum was injected only after the author had seen the patients in a typical paroxysm, and no other medication was used. The author noted carefully the number of attacks of coughing that occurred for the few days previous to the beginning of treatment, the patient keeping a record of the attacks. About ten centimeters of the serum were injected in each case, that is, one dose being given. No preventive injections have yet been made. The injections were given as early as possible in the disease. All of the injected cases were among private or dispensary patients, excepting one, which was treated in a hospital. After the injection the number of paroxysms diminished, especially at night, together with the duration of each attack. The cough was shorter, the whoop was absent, there was less fatigue, and no vomiting occurred. Expectoration was facilitated and became mucopurulent. The author believes that the remedy is of distinct value in the treatment of this disease. No bad effects have been noted.—*La Clinique.*

Foreign Physicians in Peru.—The Peruvian regulation requires that physicians who are graduates of foreign universities and who desire to practise their profession in Peru shall present themselves before the Faculty of Medicine of the University of Lima, bringing with them the diploma of the university from which they have been graduated, with the signatures properly legalized by the Peruvian Ministry of Foreign Affairs, and a certificate of personal identity issued by the minister or consul of the nation of the applicant resident in Lima. In the absence of these there must be produced a legal identification by witnesses. The fee to be paid before taking the examinations amounts to $493, which is the equivalent of the dues incurred by an alumnus receiving his medical instruction in the University of Lima. Anyone contemplating practising medicine in Peru can get information regarding these regulations from the Dean of the Faculty of Medicine of the University of Lima, Dr. Ernesto Odriozola.

PORTS OF ENTRY FOR PATHOGENIC GERMS IN ACUTE ARTICULAR RHEUMATISM.

IN a very small percentage of cases the evidence that acute articular rheumatism is set up by the entrance of a pathogenic germ through some accidental foramen in a mucous membrane seems almost conclusive. That there is nothing violent in this supposition should be apparent from the analogy of gonorrheal rheumatism which must proceed from infection through the urethra. It is none the less true, of course, that in the vast majority of cases no such infection from without can be demonstrated in connection with acute articular rheumatism which further may be widely differentiated from all forms of pseudorheumatism due to mild bacillemia, not only by the clinical picture presented but still more by the history of exposure and the evidence of a constitutional predisposition. The stubborn facts which constitute the notable exception to the type are as follows: the most clear cut cases of acute polyarticular rheumatism, including endocarditis or pericarditis, may follow at once upon a tonsillitis, intranasal lesion, or even a laryngitis, and in very rare instances may follow some cutting operation in the nose or throat.

At a recent meeting of the Verein für innere Medizin und Kinderheilkunde in Berlin (*Deutsche medizinische Wochenschrift*, February 29), Max Senator read a paper on so-called nasal rheumatism (abstracted in the MEDICAL RECORD, March 16, 1912) in which he reported a personal case fortified with two others from the literature which tended to show that a turbinectomy, even when done aseptically, may sometimes give rise at once to very severe yet typical acute polyarticular rheumatism. A full discussion followed the delivery of the paper. Gudzent had long investigated his cases of rheumatism from the tonsillar viewpoint and had isolated a series of cases presenting the association. These patients were all subjected to tonsillectomy with the hope of securing immunity from further attacks of rheumatism but all to no purpose. Although the tonsils were infected and manifestly in need of removal severe subsequent attacks of rheumatism were not prevented. A. Fraenkel went further and fared worse, for he removed infected tonsils in a patient who had not yet suffered from acute rheumatism, but was a victim of nephritis. Immediately following the tonsillectomy an acute endopericarditis developed, while the nephritis, which had always become worse with each attack of tonsillitis, suffered a marked exacerbation. Heymann saw no actual similarity between nasal and tonsillar rheumatism. The cases cited by Senator were nasal and traumatic. He had seen one case of this character, together with a nasal case which had no traumatic factor. This was one of polyarthritis which was clearly dependent on a chronic, periodically exacerbating sinusitis of the maxillary antrum. The existence of a tonsillar rheumatism had long been conceded and he had had one case of recovery following tonsillectomy. Kraus had never seen a case of rhinogenic rheumatism but said there was such an affection as laryngeal (laryngogenic), rheumatism. He would never ablate an infected tonsil while it was acutely inflamed. In his experience tonsillar rheumatism was mostly of the subacute relapsing type, connected with the presence of a pocket of pus in one of the tonsils. The indication is to deal with this pocket, not necessarily by ablation. F. Meyer studied tonsillar rheumatism bacteriologically in 1899. Since that time he has collected notes of thirty-five cases of articular rheumatism associated with lesions of the nose and tonsils. Streptococcus sore throat ought to immunize a patient against successive attacks in time, but this is open to doubt. The speaker also referred to the occasional cases of appendicitis of apparent tonsillar origin. Senator in closing referred to the association of intranasal, tonsillar, and laryngeal lesions on the one hand with articular rheumatism and appendicitis on the other as furnishing documents to the essentially infectious nature of rheumatism.

THE PHYSICIAN AS AUTOCRAT.

THE Madeira-Mamore Railway is now building in the Amazon country, in order that the products of this region, especially rubber, may the more expeditiously be conveyed to civilization. This is a region dreadful by reason of its dangers from savages, from inimical animal life, and from the poisonous vegetation; and one most insalubrious because of its equatorial fevers. There are reported by the *New York Evening Post* to be six thousand men, of most diverse races and temperaments, employed in this work; and the bodies of some two thousand more have been buried along the line, or have been sunk in the black river (the Rio Negro) or in the muddy Amazon.

Physicians are engaged to keep fever from these workers, and to dose those who have unfortunately experienced the bite of the malaria-transferring mosquito. They are medicated in order that they may work. If, however, they sicken beyond the ability for work they are humanely sent back down the river to the coast. In the Amazon jungle railway building is a matter of sanitation rather than of engineering, and the makers of the railway now under construction there, like the builders of the Panama Canal, have done what they have done with the doctor as pioneer. Each force of workers has its physician, armed with quinine in one hand, a revolver in the other, to see, as a matter of choice,

that the medical bullets enter the laborer's economy at the rate of ten grains a day; he who does not take his medicine at once, be he either digger or engineer in charge, gets his "time" and his dismissal. The physician is "boss of the line." His office or field hospital may be a palm shack or a box car; but one or the other is a part of each construction camp, and his authority is supreme. If any among those under him fall seriously sick despite his ministrations, he orders them back to the big, well-equipped modern hospital at Porto Velho, which has a force of physicians and trained women nurses, mostly from the United States. Here the Amazon mosquito is screened against. All the houses of Americans are double-screened, and even their shacks are screened. The system is not yet perfect enough to make the laborers use screens; for many among them are contemptuous of mosquitos, and quinine must give them whatever immunity they get. The latest reported order sent in by the company building this railway was for 1,000,000 five-grain capsules, which forced the recipient drug house to beg for "a few months' warning" before receiving another order of the same kind.

Here, again, in the Amazonian wilds, is demonstrated what for a score of years past has been manifest in India, in Africa, in the West Indies, and most resplendently in our Canal Zone. Formerly the hot lands were death to the white man; to-day the medical missionaries of this era are demonstrating by their practice of the modern sciences of bacteriology and prophylaxis that the Tropics can be freed of infection and pestilence, that the earth, between Cancer and Capricorn, can be made habitable for the white. When in the torrid region the doctor has done his work, the rest may safely follow—but not until then. And it is, indeed, a policy of enlightenment which prompts those exploring and exploiting the Tropics to give the physician paramount authority in these expeditions.

HUMAN BLOOD SERUM IN THE TREATMENT OF HEMORRHAGIC DISEASE AND OTHER CONDITIONS.

THERE is a large group of morbid conditions which though differing in their fundamental pathology, nevertheless present one common clinical manifestation, namely the tendency to spontaneous hemorrhage. Within recent years many cases have been reported in which successful results followed the use of transfusion of blood in hemorrhagic disease of the newborn. The tendency nowadays, however, is to substitute for the difficult methods of transfusion of blood the comparatively simple method of using ordinary human blood serum, obtained preferably from a near relative and injected subcutaneously into the affected individual. This method is equally as efficacious as the former, and its simplicity has suggested its applicability in a wide group of disorders. Not only in hemorrhagic disease of the newborn, but also in hemophilia, Henoch's purpura, and pernicious anemia, human blood serum has been employed with good results.

The expression "melena neonatorum" should be discarded in favor of the more scientific term hemorrhagic disease of the newborn, as pointed out by W. R. Nicholson, in the *Therapeutic Gazette*, February 15, 1912. In this condition the symptom hemorrhage may be but a minor manifestation of the morbid condition during life, and in fact may be revealed only on post-mortem examination. The author believes that this condition is an infective one, and that the infection enters by way of the child's mouth during the progress of parturition. He reports a case in which recovery followed the use of human blood serum.

J. E. Welch was the first to report two years ago the brilliant therapeutic results obtained by this form of therapy. In a further communication in the above-mentioned journal he states that the fundamental condition in these cases is bound up with the endothelium lining the blood vessels and a disturbance in the balance of the ferments contained in these cells is the immediate cause of the hemorrhages. This disturbance he believes is due to malnutrition. Hemorrhage so commonly observed in cases of inherited syphilis and of bacteriemia can be accounted for in this way. The condition is primarily a disease of the blood and the effect of normal blood serum in controlling these hemorrhages seems to be through the nutritional effect upon the endothelium lining the blood-vessels. The normal blood serum contains molecules whose receptors fit those of the endothelium cells. In this manner the nutritive constituents of the blood serum are capable of being taken up by the cell body without any energy being wasted in the process of digestion. The nutrition being thus easily restored, the balance of ferments is reestablished and the hemorrhage is controlled. In various hemorrhagic conditions associated with sepsis and in any other condition in which there is a disturbed equilibrium of the ferments contained in the endothelial cells the injection of human blood serum has amply demonstrated its efficacy.

UNTOWARD EFFECTS OF SALVARSAN.

NUMEROUS attempts have been made to explain certain untoward effects accompanying the administration of salvarsan; effects which are rather infrequent and but seldom serious, yet detract somewhat from the value of this sovereign remedy. The use of saline solution or of water contaminated by the bodies of dead bacteria, the failure to neutralize properly the acid solution of salvarsan, too high or too low a temperature of the solution, the administration of arsenic in other forms previous to the use of salvarsan, are among the causes of untoward effects that have been brought forward, and have in a measure explained them. That great care is needed in preparation of the salvarsan solution used for intravenous administration is further shown by the researches of R. Gonder, published in *Russkii Vrach* of February 4, 1912. Gonder has shown that solutions of salvarsan are extremely unstable in the presence of other substances, and the use of freshly distilled water is only one step in forestalling untoward effects. Thus minute traces of calcium chloride are enough to form a precipitate in a neutral solution of salvarsan, a precipitate

which may work great injury when injected because of the small emboli it causes. Salvarsan solutions containing small amounts of calcium salts proved more toxic than pure solutions of the drug.

Now, while freshly distilled water is used for making salvarsan solutions, yet the curette, needle, and syringes used are usually sterilized by boiling in tap water and in sterilizers that are frequently coated by a layer of salts deposited from previous sterilizations of instruments. Enough calcium salt may thus find its way into the instruments to increase the toxic effect of salvarsan and explain some of its injurious effects. Of course, the individuality of the patient is the deciding factor in the appearance or absence of such effects, and this may explain the difference in opinion among men who have given but a few injections and have had good or bad "luck" with them. Gonder's paper shows the minute care which is necessary in preparing for intravenous administration of salvarsan, and such care should certainly be taken in justice to the originator of the remedy, and especially in justice to the patient who submits in all confidence to the use of the new drug. Boiling instruments in freshly distilled water is surely not too complicated a procedure for well-equipped hospitals or sanatoria, and it is only in such places that intravenous injections of salvarsan should be given.

DIAGNOSIS OF TUBERCULOSIS OF THE BRONCHICAL LYMPHNODES IN CHILDREN.

Behring's contention that the gastrointestinal tract serves as the most frequent portal of entry of the tubercle bacillus in children led to a great deal of careful pathological work in Germany with the result of almost completely disproving his findings. The old belief that tuberculosis of children is usually pulmonary in origin has been strengthened, and yet the route of infection has been more clearly defined. It has been shown that the lymphnodes gathered about the hilus of the lung are frequently the primary seat of infection, tubercle bacilli inspired into the bronchi being taken up by these nodes, and finding their way thence into the pulmonary tissue or into the general circulation. The diagnosis of "hilus tuberculosis" has therefore become of great importance, but the usual physical methods of such diagnosis, however successful with some *virtuosos* of percussion and auscultation, have proved inadequate for the great majority of physicians to whom children are first brought for advice.

Writing in the *Wiener klinische Wochenschrift* of February 15, 1912, Erich Sluka shows how important in this connection are repeated *x*-ray examinations of the lungs. Of course suspicious shadows at the site of the pulmonary hilus, seen but once, may be explained by acute enlargement of the lymphnodes, such as often follows infectious diseases of childhood. When, however, the same shadows are repeatedly seen in a child who seems to be below par, perhaps coughs a little, or is slowly growing paler and weaker, tuberculosis of the lymphnodes must be suspected. That such suspicion is well warranted has been amply shown by numerous autopsies, especially by Weigert and by Hamburger, who have demonstrated tuberculous infection of the lymphnodes in children in whom the infection runs a latent course until the final catastrophe in the shape of an acute miliary tuberculosis of the lungs or of a tuberculous meningitis. These accidents may be interpreted as massive autoinfections, a wall of a blood-vessel or of a bronchus being slowly eroded by the progressive caseation of a neighboring lymphnode. The *x*-ray examination should serve, then, more or less as a prophylactic measure. While existing tuberculosis of the lymphnodes may be shown by it, further damage may be prevented by the usual hygienic and sanitary measures and especially in shielding the child from such infections as measles, whooping-cough, etc., that break down his partial immunity to the spread of tuberculosis.

Nephrotyphus.

That Eberth's bacillus is able to attack the organ of least resistance and give rise to the picture of a localized affection is of course well known. We have pneumotyphus and pleurotyphus and cholecystitis typhosa, which may be part of an ordinary typhoid syndrome or a purely isolated lesion, recognizable only through the agglutination test and the presence of the bacillus in the secretions. That the kidneys should be attacked by the latter is not strange, for the case is known with which the *Bacillus coli* can set up both ascending and descending pyelonephritis, the latter apparently through lymphatic propagation from the intestine; and it might be supposed that Eberth's bacillus is sometimes capable of similar pathogenicity. But a case recently described by Pollitzer at a medical meeting in Vienna (*Berliner klinische Wochenschrift*, Feb. 12) seems of a different character, and one which deserves especially the designation nephrotyphus. The patient, a woman, was taken with a chill and other evidences of toxemia, enlarged spleen, and pain in the left lumbar region. There was albuminuria. The diagnosis having been placed beyond doubt, the author seeks to explain the peculiar course of the disease by the vagotonic constitution of the patient.

Athletes and Long Life.

In answer to the query, "Do athletes die young?" Dr. William G. Anderson, director of the Yale University gymnasium, has given the results of a study of the college records for fifty years. A comparison of the mortality of specialized athletes with the general graduate who has not distinguished himself in athletics shows in favor of the athlete. Of 10,922 students in academic and Sheffield classes from 1855 to 1905 inclusive, 1,406 have died, and 9,516 are still living. This shows the percentage of deaths to be 12.6 per cent. Of the 207 athletes from 1855 to 1905, only 58 are dead, a percentage of 7.2, or a little over half that of the general graduates. Dr. Anderson concludes that the Yale athletes do not die young, nor is heart disease a leading cause of death in them. Lung trouble is the cause of the greatest number of deaths, but the percentage of men dying from these causes is not greater than the expected death rate among non-athletes from similar causes. However, although the athlete is not short-lived, the statement is not warranted that he owes his longevity to athletics.

News of the Week.

Practical Eugenics.—From Chicago comes the announcement of a definite step in the direction of the control of marriage, the dean of the cathedral of the Protestant Episcopal Church in that city having declared that henceforth no marriages shall be permitted in the cathedral unless both the man and woman are able to present certificates of health from a reputable physician to the effect that they are normal physically and mentally, and are not suffering from an incurable or communicable disease. This step, the dean announces, has been taken only after months of study of the situation, and it is believed that the stand will meet with the approval of the clergy generally, all of whom must have long felt the undesirability of being a party to the marriage of persons who, because of their physical condition, should never be allowed to enter the married state. The innovation has resulted at least in much discussion of the subject, the approval of many being freely given, and the practicability of the plan only being called into question.

Measles Prevalent.—Reports of the Department of Health of New York show that there are about twice as many cases of measles in the city as during this time last year, although the department does not admit that there is anything approaching an epidemic. During January and February there were 6,860 cases of the disease reported, as against 3,006 for the same months of 1911.

For Pure Water.—Provision for the protection of the Croton water supply and of all water supplies in the State which are drawn from watersheds traversed by railroads is made in a bill introduced in the New York Legislature on March 27. The bill provides that after January 1, 1913, the cars of every railway crossing a watershed from which any public or private water supply is obtained must be so equipped as to prevent all possibility of contaminating the supply.

Smallpox Epidemic.—There were at the end of March twenty-three cases of smallpox in Naugatuck, Conn., eleven cases having developed within a short time.

Surgery Under Difficulties.—While the surgeons were at work in the operating room of the Bushwick Hospital, Brooklyn, on March 26, a fire broke out in another part of the hospital building, a frame structure accommodating twenty-six patients. The fire was extinguished before great damage was done and without the necessity of removing any of the patients, and the operation was continued through the excitement of clanging bells and shouting firemen, although the dense smoke made it necessary to open windows in the operating room.

Newspapers Help Tuberculosis Fight.—According to an estimate of the National Association for the Study and Prevention of Tuberculosis, one and a half million inches of space in the columns and newspapers of this country are devoted each year to aiding by publicity in the fight against tuberculosis.

Wood Alcohol Poisoners.—In Berlin, Germany, five men accused of being responsible for wood alcohol poisoning of many inmates of the Municipal Night Shelter for the Homeless in the city were placed on trial on March 26. The indictment specifies eighty-nine deaths and five cases of total blindness. The charges are of violation of the pure food law and fraud merely. The accused includes a druggist who prepared the poison and two saloonkeepers who mixed and sold the stuff as rum and other popular cheap drinks.

Radium Standard.—It is stated that at the request of the international commission for fixing a radium standard, Mme. Curie has prepared a glass tube three centimeters long and three millimeters in diameter, and that the exact amount of radium contained in this tube will be fixed as the standard of weight.

Heredity and Hare Lip.—Dr. Charles B. Davenport and Dr. W. F. Blades of the Eugenics Record Office, Cold Spring Harbor, N. Y., announce that they are engaged in a study of heredity of hare lip, cleft palate, and associated malformations of the oral cavity, and they solicit correspondence with physicians who can supply histories of families more than one member of which has an oral defect. Such data will be held as strictly confidential and will be used solely to aid in the solution of a problem which is of humanitarian as well as of scientific interest.

Candidates for Nobel Prize.—The Academy of Science, the Medical Faculty of the University of Havana, and several other scientific societies and institutions have passed a joint resolution in which the names of Dr. Carlos J. Finlay and Dr. Aristides Agramonte are presented to the Nobel Prize Commission as candidates for the prize to be awarded in 1912. The resolution points out that Dr. Finlay was the first to claim that yellow fever is transmitted by the mosquito, while Dr. Agramonte is the sole survivor of the United States Army Board composed of Drs. Reed, Carroll, Lazear, and himself, which demonstrated the correctness of this theory. It is suggested that the prize for this year be divided between these two men whose work was thus so directly complementary.

Resignation of a Hospital Staff.—The entire consulting staff, consisting of ten physicians, of the Municipal Hospital for Tuberculosis of Lawrence, Mass., has resigned. The trustees of the hospital have also retired, the action of all being taken because of the decision of the director of public health in determining that the hospital should come under the direction of the city physician and his staff.

Charitable Gifts.—The Northumberland and Durham County (Ontario) Councils on March 12 decided to accept the first plan of Mr. John Helm's will, by which the Port Hope Hospital receives $20,000; the Cobourg Hospital, $20,000; the Hospital for Sick Children, Toronto, $6,000; the Toronto General Hospital, $50,000, and the Muskoka Free Hospital at Gravenhurst, $6,000. The alternative offer was $100,000 for the establishment of a hospital in Port Hope, and the decision as to which was the better plan was left to the Council. The American Museum of Safety has received a gift of $5,000, which will enable it to purchase the famous Sommerfield collection of wax models illustrating occupational diseases and industrial poisons, now in the Berlin Museum of Safety. The collection will probably be installed in the fall. By the will of the late Walter D. Lebrenz of Philadelphia the sum of $1,000 is bequeathed to the Rush Hospital for Consumptives.

New Hospital for Colored Persons.—The new hospital building for the Leonard School of Medicine of Shaw University, Raleigh, N. C., has just been completed at a cost of $47,000. It is operated in connection with Shaw University, the Baptist

school for negroes at Raleigh, and is entirely for the treatment of negro patients.

To Enlarge a Medical Library.—The Hartford (Connecticut) Medical Society, at its meeting on March 18, voted to build an addition on the rear of the Hunt Memorial building, which will cost about $12,000 and will be large enough to house approximately 05,000 volumes. The building will be of fireproof construction, and will probably be ready about September 1.

A Graduate School of Medicine at Harvard.—In accordance with a recommendation from the Faculty of Medicine, the Corporation of Harvard College voted on May 8, 1911, to establish a Graduate School of Medicine. This school will take control of all graduate instruction in medicine October 1, 1912, and will be administered by a separate Dean and Administrative Board. It will thus be on an equality with the Medical School proper and the Dental School. Dr. Horace D. Arnold of Boston has been appointed Dean of the Graduate School. The work of organization has begun and plans are being developed which promise to make this an important move in medical education.

Memorial to Dr. Long.—On March 30 there was unveiled at the University of Pennsylvania a bronze medallion in memory of Dr. Crawford Williamson Long, who was graduated from the medical school in 1830, and who, on March 30, 1842, just seventy years before, for the first time in the history of surgery, made use of ether as an anesthetic for surgical purposes. The medallion, which was sculptured by Dr. R. Tait McKenzie, was unveiled in the hall of the Medical Laboratories Building, and addresses were made by Dr. J. William White, former professor of surgery at the University of Pennsylvania, and by Dr. J. Chalmers Da Costa, professor of surgery at the Jefferson Medical College, Philadelphia.

Sir Bertrand Dawson, Surgeon to King George of England, arrived in New York on March 29 by the steamship *Mauretania* on a tour of inspection of hospitals and medical institutions in this country.

Dr. Joseph S. Gibb of Philadelphia has resigned his professorship of diseases of the nose and throat in the Philadelphia Polyclinic and has been elected professor emeritus.

Dr. Elie Metchnikoff, director of the Pasteur Institute of Paris, has been elected a member of the French Academy of Sciences.

The Fifth Weir Mitchell Lecture of the College of Physicians of Philadelphia was delivered on the evening of March 29 by Dr. Wm. H. Howell, Professor of Physiology in Johns Hopkins University, and dealt with the subject of "The Factors Concerned in the Coagulation of Blood and Their Variations under Pathological Conditions." He pointed out that fibrin, on which blood coagulation depends, was a product of the interaction of fibrinogen and thrombin in the presence of calcium. The fibrinogen is a soluble proteid present in the blood, while the thrombin is preceded by a substance prothrombin derived especially from blood-platelets and activated by thrombokinase or thromboplastin, a derivative of blood-cells and tissue-cells. In addition the blood contains a substance, antithrombin, which acts normally as a corrective in the direction of antagonizing clot-formation. Changes in the proportions and activity of these several bodies play some part, not entirely demonstrable, in the mechanism of conditions like thrombosis and of diseases like purpura.

Dr. Fred Brush has resigned the superintendency of the New York Post-Graduate Medical School and Hospital, to become superintendent of the Burke Relief Foundation, and engage in the planning and organization of the Convalescent Hospital, to be erected at White Plains, N. Y., on the sixty-acre plot of land recently purchased. McKim, Mead & White are the architects, and a new type of institution and work for the care of the city's sick will be established.

Dr. R. M. Pearce, Professor of Research Medicine at the University of Pennsylvania, will deliver at the Syracuse Medical School the annual Alpha Omega Alpha address of the Gamma of New York Chapter. The title of the address is "Medical Education." The address will be delivered at the annual public meeting of the chapter at 8:30 P.M. At 6:30 P.M. Dr. Pearce will be the guest of honor of members of the fraternity at their annual dinner.

The Polyclinic Hospital.—The Trustees and Medical Staff of the Polyclinic Hospital invite the members of the medical profession to an inspection of their new building, 341-351 West 50th street, from 3 to 6 P.M., on the 17th, 18th, 19th and 20th of April. The hospital will be opened for patients on April 22. The ambulance service will be inaugurated on May 1. The formal dedication of the school and hospital buildings will take place on Saturday, June 8, the day after the adjournment of the annual session of the American Medical Association.

Ambulance Crash.—While crossing Fourth avenue, Brooklyn, an ambulance from the Norwegian Hospital in that city conveying a patient to the hospital, came into collision with a Fifth avenue trolley car and was wrecked. The patient, a baby of two years, and the driver were unhurt, but the ambulance surgeon, Dr. Carter, suffered two broken ribs and internal injuries.

"Healer" Found Guilty.—Willis Vernon Cole, a Christian Science practitioner, on trial in the Criminal Branch of the Supreme Court of New York, was on March 30 found guilty of violating the statute relating to the practice of medicine, the jury reaching this verdict after only forty-five minutes' deliberation. As this was a test case Justice Seabury imposed a nominal fine of $100, and the case will doubtless be carried to the higher court. The defendant, during the course of the trial, admitted that he had had over 3,000 professional visits in a year.

Endowment Fund for Homeopathy.—A movement is reported to be on foot having for its object the raising of a $1,000,000 fund to be used for the endowment of homeopathy in the United States.

American Medical Editors' Association.—The annual meeting of this society will be held at Atlantic City, N. J., on June 1 and 3, with headquarters at the Marlborough-Blenheim Hotel. An attractive program is being prepared. The annual banquet will be held on the evening of June 3. Every editor and those associated in medical journalistic work are cordially invited to attend and take part in the proceedings.

The Harvey Society.—The Annual Meeting of this society will be held at the College of Physicians and Surgeons, 437 W. 59th street, on Wednesday, April 10, at 8:30 P.M.

South Carolina Medical Association.—The annual meeting will be held in Columbia on April 16 to 18, under the presidency of Dr. J. Wilkinson Jervey of Greenville. Dr. E. A. Hines of Seneca is the secretary of the society.

Ninth District (Georgia) Medical Society.—At the annual meeting held in Gainesville on March 21 the following officers were elected: *President*, Dr. Vincent D. Lockhart of Gainesville; *Vice-President*, Dr. L. C. Allen of Hoschton; *Secretary-Treasurer*, Dr. A. D. White of Gainesville.

Prof. Adelchi Negri, famed for his studies on rabies and for the discovery of the so-called Negri bodies, died in Pavia, Italy, on February 10. For many years an associate of Professor Golgi in the Institute of General Pathology at Pavia, Professor Negri contributed greatly to the elucidation of many problems in pathology and bacteriology, and, in addition to his studies in rabies, had made valuable observations on the structure of glands and of the red cells, on the activity of vaccines, on the filtration of vaccine virus, and on the regeneration of the parathyroid.

The Late Dr. John S. Hawley.—The Hospital Graduates Club desires to place on record its sense of loss in the death of Dr. John S. Hawley. Dr. Hawley was one of the corporate members of the organization and at his own request was transferred to the associate list in March, 1891. Though of late years he was unable to meet with us often, owing to ill health, his colleagues, especially the older members, entertain a lively recollection of his admirable traits of character. He was the soul of honor, abominated all pretense and professional bombast, had in his make-up an unusually large amount of the milk of human kindness, and was ever ready to help those less fortunate in life than himself. Withal he was a keen wit and on the social occasions of the club was ever ready to contribute to the success of its programs. Some of his contributions are indeed memorable in the literary efforts of the local medical profession. We shall always remember his genial disposition, good fellowship, and lovable traits of character. Therefore be it *Resolved*, that this tribute be entered in full on the club records, and *Resolved*, that it be published in the local professional journals and a copy sent to the survivors of Dr. Hawley's family. (Signed) James E. Newcomb, Arthur B. Townshend, William Kelly Simpson, Committee.

Obituary Notes.—Dr. James H. Sternberg of Waterloo, N. Y., a graduate of the Jefferson Medical College, Philadelphia, in 1856, died on March 26, after a short illness, aged 79 years.

Dr. Edmund K. Goldsborough of Washington, D. C., a graduate of the Medical College of Virginia in 1864, a surgeon in the Confederate Army after his graduation, and for many years a practitioner in Washington, died at his home after a short illness on March 14, aged 69 years.

Dr. Jessup David Bell of San Antonio, Tex., a graduate of the Pulte Medical College, Cincinnati, Ohio, in 1890, and a member of the American Medical Association and the Texas State and Berear County Medical Societies, died at his home of pneumonia on March 10, aged 44 years.

Dr. Floyd W. Rogers of Newport, R. I., a graduate of the University of Maryland School of Medicine, Baltimore, in 1902, and a member of the American Medical Association and the Rhode Island State and Newport County Medical Societies, died at the Newport Hospital, on March 26, aged 53 years.

Dr. Alonzo D. Hill of Dexter, Mo., a graduate of the Miami Medical College, Cincinnati, in 1866, died after a short illness, on March 24, aged 75 years.

Dr. Alexander E. Garceau of San Francisco, Cal., a graduate of the University of Vermont College of Medicine, Burlington, in 1881, and a member of the American Medical Association, and the California State and San Francisco County Medical Societies, died after a short illness, on March 14, aged 58 years.

Obituary.

JOHN HERR MUSSER, M.D.

PHILADELPHIA.

Dr. John H. Musser died suddenly from heart disease at his home in Philadelphia on Wednesday of this week, at the age of 55. He was born in Strasburg, Pa., in 1856, obtained his medical degree from the University of Pennsylvania in 1877, and had practised in Philadelphia ever since. Dr. Musser was a Professor of Clinical Medicine in the University of Pennsylvania, and was connected with the Philadelphia, University, and Presbyterian hospitals. He was a member of the Philadelphia County Medical Society, the Medical Society of the State of Pennsylvania, the American Medical Association (of which he was president in 1904), the College of Physicians of Philadelphia, and a number of other societies, local and national.

Dr. Musser was especially noted as a diagnostician, and had contributed much of great value to this branch of medical literature. He came from a long line of practitioners, not only his father, but his grandfather and great-grandfather having been physicians.

Correspondence.

GONORRHEAL AUTOTHERAPY AND BUCCAL GONORRHEA.

To the Editor of the Medical Record:

Sir:—Whatever may be said of Dr. Charles H. Duncan's paper in the Medical Record of March 30, "Gonorrhea: Its Prevention and Cure by Autotherapy," it is certainly unique. I am not ready at this moment to criticise it. The author's three cases are not only insignificant in number but are in themselves inconclusive. Still I do not belong to those who will condemn and ridicule a treatment merely because it is novel and at first glance looks somewhat bizarre or even absurd. There is one statement, however, to which I wish to take exception. It is the statement that "the possibility of gonorrheal infection of the mouth is so slight as to be practically disregarded." That gonorrhea of the mouth is rare is true, but that the danger of infection is so slight as to be disregarded is far from being true. The author has apparently not studied the literature of the subject very thoroughly. Otherwise he would know that undoubted cases of gonorrhea of the mouth have been reported. It is sufficient to mention Dohrn, Cutler, Hölder, Widal, Petit, Colombini, Jurgens, etc. It must also be borne in mind that the conditions for buccal infection were never so favorable as those that would prevail if the author's method of treatment would become universal. Even the lowest prostitute would object to practise coitus *ab ore* with a man suffering from gonorrhea in the active stage. And to deposit pus teeming with gonococci on the tongue or the oral mucous membrane, containing perhaps fissures or erosions, is certainly a risky procedure. Of course the pus could be administered in pill or capsule form, but this is an-

other matter. I repeat, I am not in any way discussing the therapeutic value of this unique method. I am only objecting to the author's minimizing the dangers of buccal infection or the prevalence of buccal gonorrhea.

WILLIAM J. ROBINSON, M.D.
12 W. MORRIS PARK WEST.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

VIVISECTION COMMISSION'S FINAL REPORT—HOSPITALS AND INSURANCE ACT—ST. GEORGE'S HOSPITAL LABORATORY QUESTION—ELEPHANTIASIS TABLET TO LISTER IN R. C. S.—BATH MINERAL WATER — TELEPHONES AND TUBERCULOSIS—OBITUARY.

LONDON, March 15, 1912.

THE Royal Commission on Vivisection, which was appointed in 1906, has at last issued its final report. The document has only been in circulation a couple of days, and expressions of public opinion are generally favorable to it as the result of an impartial and thorough inquiry. It is true that the voice of the fanatics is being raised by the officials of their societies who may find their salaries in danger, for the report is a heavy blow to the antis. The main conclusion reads thus: "After full consideration we are led to the conclusion that experiments upon animals, adequately safeguarded by law faithfully administered, are morally justifiable and should not be prohibited by legislation." The Commission finished taking evidence in March, 1908. The evidence taken extends through five bulky blue books, and some time was lost by the decease of the first chairman rendering it necessary to go over much work a second time. The following are the recommendations of the Commission: (1) An increase in the inspectorate; (2) further limitations as regards the use of curare; (3) stricter provisions as to the definition and practice of pithing; (4) additional restrictions regulating the painless destruction of animals which show signs of suffering after experiment; (5) a change in the method of selecting and in the constitution of the Advisory Body to the Secretary of State; (6) special records of experimenters in certain cases. The eight members of the Commission sign the report, which may therefore be called unanimous; but three make some reservations, and one of these has written a further memorandum as long, almost, as the report itself. As to the above recommendations, on (1) the appointment is advised of a whole-time chief inspector and three others, or of such a number of part-time inspectors as would be equivalent, and they should be "qualified medical men of such position as to secure the confidence both of their own profession and the public"; on (2) there is some difference of opinion, but it is agreed that if curare is to be permitted an inspector or a nominee of the Secretary of State should be present and satisfy himself that the animal is throughout completely anaesthetized. Further, as to safeguards against pain, it is recommended that an inspector should have power to order painless destruction of any animal which shows signs of considerable pain after experiment. Also, the experimenter himself should so destroy an animal suffering severe pain which is likely to endure, although the object of his experiment has not been attained.

In commenting on the evidence the Commissioners declare they believe that holders of licenses and certificates have with rare exceptions endeavored with loyalty and good faith to conform to the law, and they condemn the methods of the fanatics thus: "We desire to state that the harrowing descriptions and illustrations of operations inflicted on animals, which are freely circulated, are in many cases calculated to mislead the public, so far as they suggest that the animals were not under an anaesthetic. To represent that animals subject to experiment in this country are wantonly tortured would, in our opinion, be absolutely false." The evidence of some of the antis is closely analyzed, *e.g.* Mr. Coleridge's complaint about Dr. Schäfer's drowning experiments is disposed of in this way: The certificate authorized ten unanesthetized dogs being submerged and resuscitated. Only two, however, were used, and both were drowned without resuscitating, and "so far as we can judge, suffered no more pain than stray dogs that are destroyed by drowning." Of one of Miss Hageby's cases the Commissioners say: "It is obvious that this statement was founded on a misapprehension on the part of Miss Hageby, who mistook." * * * Concluding this part, the Commissioners say: "The witnesses have either misapprehended or inaccurately described the facts."

Under the heading "Progress of Science and Results of Experiments" we are told that notwithstanding some failures, valuable knowledge has been acquired in regard to physiological processes and the causes of disease. Further, "useful methods for the prevention, cure, and treatment of certain diseases have resulted from investigation on living animals, and there is ground for believing that similar methods, if pursued in the future, will be attended with similar results."

With regard to the classes of animals on which experiments might be made there were differences of opinion in the Commission. Some would prefer the protection granted to horses, asses, and mules should be extended to dogs, and some would like dogs to be excluded altogether from experimentation. But "if any alteration be made in the existing procedure the majority would agree that the special enactments now applicable to horses, asses, and mules might be extended to dogs and also to cats and anthropoid apes."

In the House of Commons a motion on another subject having been ruled out of order gave an opportunity for a motion, of which notice had been given, to exempt altogether the dog, as the "particular friend of man," from experiments. This was urged by one who did not object to vivisection in other cases. Mr. McKenna, for the Government, declined to express any opinion on the ground that the Commissioners' report had only appeared that morning, after six years' investigation, and there had been no time to give it due consideration. The subject was, therefore, dropped.

At hospital meetings the effect of the Insurance Act is generally referred to as injurious. The Hon. A. Brodrick, presiding at R. Westminster Ophthalmic Hospital, said everyone connected with hospital administration must feel its effects. Mr. Lewis, in seconding the report, said he was afraid the voluntary hospitals would shortly have to be taken over by the State, and then they would be managed in the way the State usually managed such institutions. Sir E. H. Currie suggested that, as the hospital had a discretionary fund, it might be as well to charge that with the bacteriological expenses—a suggestion the treasurer said his committee would consider.

You may remember that the Lord Mayor under-

took to inquire into the allegation that St. George's Hospital spent too much on the bacteriological and pathological departments, for which reason the King's Fund withheld their grant. At the meeting of the council of the Sunday Fund at the Mansion House last week the Lord Mayor reported that he had carefully investigated the matter and was convinced that the work done in these departments is as necessary as in others for the welfare of the patients, that the proportion paid by hospital and school is a fair one and the sums expended by the hospital are properly taken from the general funds, being for the direct treatment of the patients.

A supplement to the *Journal of the London School of Tropical Medicine* is devoted to the report of Dr. P. H. Bahr on Filariasis and Elephantiasis in Fiji. He urges that destruction of mosquitoes should be efficiently carried out as the only known means of prevention. He points out that the pathological expression in the Fiji islands as elsewhere is elephantiasis; that the precise method of its production has yet to be determined; that a large proportion, 27.1 per cent., of Fijians harbor microfilariæ in their blood and there are reasons for believing that, at one time or another, nearly every Fijian is the subject of filariasis; that the evidence is insufficient to decide whether or no the filaria in Fiji is a new species; and medicinal doses of parasiticide drugs have no manifest influence on the circulating microfilariæ.

Yesterday at the Royal College of Surgeons the council passed a vote of condolence with the relatives of the late Lord Lister. The college is a specially appropriate place for the recognition of his great work, but you may take it that not only in all surgical, medical, or scientific institutions has his death called forth expressions of admiration but similar testimonies have been offered in public assemblies of all kinds, not only here but in all countries. The council also decided to place a tablet in a suitable position within the walls of the college "to serve as evidence to future generations of the honor, respect, and reverence in which the great founder of aseptic surgery was held by his contemporaries and immediate successors."

Sir William Ramsay has been investigating the mineral waters of Bath and on Monday gave an account of his research at a public meeting of the Corporation. He has found an appreciable quantity of niton and gave a full exposition of this radium emanation, sufficiently technical to puzzle the general reader. So all the week the newspapers have been endeavoring to explain the properties of this substance and to illustrate the infinitesimal quantities in which it can produce effects. The people of Bath are delighted to have a new reason for the efficacy of their Spa and especially to learn that the niton in the gas of their waters is four times greater than in that of Buxton.

In consequence of statements as to the possibility of transmitting tuberculosis through telephone mouthpieces, Dr. Spitta for the postmaster-general has carried out an investigation at St. George's Hospital. The work was carried on throughout the year 1911 and a final report has now been received from Dr. Spitta showing the results to be all negative. Not only were telephones in ordinary use examined but some in a sanatorium used only by patients and neither cleaned nor disinfected during the course of the inquiry. Dr. Spitta concludes that "the transmission of tuberculosis through the medium of the telephone mouthpiece is practically impossible." I think a similar result was obtained from an inquiry on your side some time ago.

Surgeon Lieut.-Col. Edward Mason Wrench, F.R.C.S., J.P., died on the 12th inst. at the age of seventy-eight. He was a surgeon in the Crimean War and after retirement often lectured on that campaign. He was a member of the Royal Victorian Order and a magistrate and was medical attendant to King Edward when His Majesty was at Chatsworth.

Lieut.-Col. F. Gillespie, late A.M.S., died on the 7th inst., aged seventy-four. He was formerly assistant-surgeon at the Royal Military College, Sandhurst. He qualified at the Dublin Hall in 1858 and R. C. S. Ed. 1860. That year he took also M.D. St. Andr. and joined the army medical staff. He retired in 1886.

OUR PARIS LETTER.

(From Our Regular Correspondent.)

RADIOGRAPHY OF THE VISCERA—THE LIFE OF THE TISSUES OUTSIDE THE BODY—DETERMINING CAUSES OF SEX—OBITUARY.

PARIS, February 20, 1912.

At the Society of Internes a very interesting discussion took place on the radiography of the viscera. The Röntgen rays for a long time served only for the diagnosis of osseous lesions. At the present time the perfection of the apparatus used allows us to obtain clear images of the viscera, so that radiodiagnosis may be constantly used to confirm the clinical diagnosis or change it if necessary. Radioscopy and radiography of the lung in the normal state permit us to note the perfect transparency of the pulmonary field, the movements of the diaphragm, the depth of the costodiaphragmatic sinus; the affections of the lungs and pleura are shown by radiography; tuberculosis at first shows itself by the obscurity of the pulmonary field and a lessening of the amplitude of the movements of the diaphragm. At a more advanced stage cavities can be easily diagnosed. Abscesses of the lung, hydatid cysts, and cancers of the lung give clear images.

In the mediastinum strictures, deviations, and dilatations of the esophagus are easily seen after the administration of bismuth. The examination of the heart allows us to get valuable information, especially of the deviations of that organ. For the lesions of the aorta the *x*-rays constitute a very important means of detecting lesions of that artery from simple dilatation to the largest aneurysm. The stomach may be studied in a most interesting way after the ingestion of milk of bismuth. We can note the time which a meal remains in the stomach, and the evacuation of liquids from the stomach, and from this may deduce the presence or absence of a pyloric lesion. The successive examination of the patient in the upright position and then lying down shows considerable morphological differences which up to the present time have been unknown. The large intestine may be studied after an injection of bismuth and we may thus detect strictures, adhesions, and dilatations of the large intestine, as well as deviations due to the development of a tumor. The liver, which is a dark organ, may be studied by radiography; it may be displaced, elevated, increased, or diminished in volume. Its lower border may be easily recognized when the stomach is inflated.

The urinary apparatus has benefited considerably

by radiography, especially since rapid radiography has permitted us to photograph organs in perfect immobility. Urinary calculi are very well seen by radiography and can be studied as to their number, volume, and position. The new improvements of radiography have also enabled us to recognize the form of the kidney, its direction, and volume, and to know whether the kidney is small or large and whether the direction of its axis is normal or not. Still there is much difficulty in the interpretation of the shadows in the lower ureteral region. To make a diagnosis of an abnormal shadow in the pelvis and not be deceived into believing in a calculus that does not exist, we must make several plates, place in the ureter a sound that is opaque to the rays, or make an intraureteral injection of collargol, so as to guard against diverticula of the ureter. We see how numerous are the visceral affections which are recognizable by radiography and how far the science of röntgenology is of service to the clinician.

At the Academy of Medicine, Pozzi reported the new experiments by Carrel on the life of tissues outside the body—matters, of course, familiar to American medical men, since the experiments were made in New York.

The causes of the determination of sex have been discussed in an interesting way by Jules Regnault, Professor of Anatomy at Toulon in the *Clinical Journal*. Among the numerous theories that have been advanced to explain the formation of sex there are few which deserve recognition. We may retain certain points that seem established. The unripe ovule which contains lecithin produces a female; the ripe ovule in which lecithin is replaced by fatty acids give a male. Russo has made experiments in rabbits by injecting lecithin into the mother only, and obtained a large proportion of females; when he injected lecithin in both father and mother he got almost exclusively females. When the female is young and its organic combustion is complete and rapid, the spare elements such as lecithin are rare, or rapidly transformable, so that the maturation of the ovule is more rapid and we have a greater chance of having fecundation produce a male. Determination of sex seems to be in relation with the greater or less maturity of the sexual element and seems to depend on the greater or less equilibrium of the internal secretions of the parents. Various diets or methods of treatment, especially opotherapy, the employment of glandular extracts, variable according to the case, put the parents in a better condition to get an infant of one or the other sex.

Albarran, Professor of Diseases of the Urinary Passages of the Hôpital Necker at Paris, has died prematurely at the age of 52 years. Albarran inherited the difficult position of Guyon. His rich scientific past, his competence in the specialty to which he had devoted his life, his world-wide fame, made him certain of the votes of the *Faculté*. Made first interne at the age of 24, four years later he obtained the gold medal of the "internat." At 30 years he was chief of clinic for diseases of the urinary passages; at 32 he was made assistant professor; at 34 he was surgeon to the hospitals. Lastly, it was in full strength and maturity that he was called to put on the purple and become the chief of the Necker school, which under his revivifying impulse was to become still more active. This rapid and brilliant career resulted from the great natural gifts of Albarran. Indefatigable worker, marvelously served by a quick and perfect intelligence, he had studied all branches of his specialty, and there is no subject in urinary surgery on which his works are not known. As well by his anatomical researches as by his patient experiments in physiological pathology, and as much by the importance of his works as by his manual ability. Albarran was truly a master. At the international congresses one might readily note the interest he impressed on the scientific discussions, with what attention his words, warm, vibrating, persuasive, were received by all, with what authority he was appreciated and how he could popularize abroad French science. But besides these qualities of the public man, Albarran possessed other virtues which were concealed from those who did not approach him closely. His pupils, especially his friends, alone knew him; the qualities of the heart and the treasures of disinterested devotion he gave out with both hands, with magnificent prodigality. It was necessary to see him when he wished to oblige one of his friends to know how he gave everything, not sparing his time, his health, his attention, as if he were dealing with one of his own family, to understand how he made profound friendships, living and strong. Undoubted master, Albarran could only dignify further the illustrious professorship which he had won. For three years Albarran had known that he had an incurable malady and was one of those whom death sought before his time, but his courage was firm and his heart heroic. He saw death approach with sadness, but without fear and with the tranquil courage of those who have the intimate consciousness that they cannot perish altogether. His contributions to science will remain as the model of their kind, and the name of Albarran will be imperishable.

REPORT OF THE MEETING OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE. (*Continued*).

(From Our Manila Correspondent.)

HONGKONG, Jan. 27, 1912.

Third Day.

THE first paper read at this session was one entitled "Studies in the Multiplication of Amebæ of the Human Intestine," by Dr. A. Gaudu cheau, Major, Medical Corps, French Army. Dr. Gaudu cheau stated that he had made a series of experiments from which he concluded that trichomonas is one stage of an ameba. In the cases of amebic dysentery which he had studied he is satisfied that in the cultures which he obtained from the ameba of the stools, such morphological change actually took place. In the discussion which followed the trend of opinion was to the effect that, in view of the fact that he made his cultures with amebæ which he obtained from amebic stools, even if the biological phenomena took place such as he claimed, it was not likely to be associated with amebic dysentery, because, so far, it has been impossible to cultivate pathogenic amebæ.

The next paper was "An Experimental Study of the Action of Ipecacuanha on Amebæ," by Captain Edward B. Vedder. The author stated that amebæ in bouillon cultures were found dead at the end of twenty-four hours, with ipecac of an alkaloidal strength of 1.80 per cent. in dilutions even as great as 1 to 10,000. Emetin, similarly

employed, was efficacious in dilutions of 1 to 100,000. He also gave a series of clinical cases in which ipecac had been used with almost complete success, and expressed the opinion that, when properly administered, it is the best remedy which can be employed for this disease.

The next paper was entitled "The Surgical Treatment of Dysentery," by Dr. O. Muller. Dr. Muller gave a series of cases of both amebic and bacillary dysentery, in which appendicostomy followed by quinine irrigations had resulted in complete success after medical treatment had failed, and he made an earnest plea for the early resort to surgical means instead of depending upon slow and uncertain medical treatment.

The next paper was "A Contribution to the Study of the Bacteriological Diagnosis of Cholera," by Professor Teruchi. Dr. Teruchi exhibited a powder which could be used as an agglutinating agent in bouillon cultures of cholera for making a microscopical test for the presence of cholera vibrios. Upon adding the powder to the culture in a test tube a thick, flocculent precipitate formed which could easily be observed with the naked eye.

The next paper read was entitled "A Preliminary Report on the Source of the Human Liver Distome," by Dr. H. Kobayashi. The author expressed the belief that the distome, as it is found in Japan, could almost invariably be traced to the ingestion of raw fish.

The next paper was entitled "Intestinal Parasites of Man in Hongkong," by Dr. J. Bell. This was illustrated by lantern slides and gave a brief account of the usual intestinal parasites that are found in the Far East. Sixty-eight per cent. of the persons examined were afflicted with some form of intestinal parasite.

The next paper was entitled "Immunization Against Pneumonic Plague," by Dr. Richard P. Strong, which was read, in the absence of Dr. Strong, by Dr. Paul C. Freer. The author gave a brief review of the unsatisfactory scientific results which had been obtained by the use of immunizing measures which depended upon the use of dead cultures of plague organisms, and he expressed the conviction that in order to produce a thoroughly satisfactory immunizing substance, attenuated, living plague organisms would have to be used. In the discussion which followed the majority of the speakers were of the opinion that, however valuable immunizing substances for the prevention of plague might be, we must not lose sight of the fact that even repeated attacks of plague do not confer immunity beyond a few months at most, and that it is too much to hope that an artificial product can be prepared that has a greater immunizing power than the immunity which nature confers after attacks of a dangerous communicable disease.

The next paper was entitled "The Connection Between Man and Rat in the Plague Epidemic in Malang, Java, During 1911," by Dr. W. L. deVogel. This paper was illustrated with lantern slides, and was a most convincing confirmation of the now generally accepted theory that the transmission of bubonic plague is due to fleas. Dr. deVogel showed numerous photographs in which persons had died of plague, and upon removing the ceiling immediately over the bed of the deceased there were found many rats dead of plague. In other instances dead rats were found in the walls alongside of the beds in which persons had died of plague. The author inferred that upon the death of the plague infected rats the fleas must have deserted their host and found their way to the bodies of the persons who had been stricken. He also showed a most interesting map of one of the provinces in Java upon which was indicated all the places at which large deposits of rice imported from Rangoon was stored, and in a different color he indicated thereon the houses in which cases of plague had occurred. In almost every instance the disease prevailed in the neighborhood of such rice storehouses, and no cases were found where these did not exist.

The introduction of plague into Java is also interesting, in view of the fact that it has been frequently asserted that Java's freedom from plague, which she enjoyed up to 1911, was attributable to the intense heat which always prevails, owing to Java's proximity to the equator. That it only needed the introduction of plague infected rats was most conclusively demonstrated by the experience of the past year. Java's experience is also another concrete instance of the value of modern quarantine measures; so long as the introduction of plague infected rats was prevented complete freedom was enjoyed, but when these passed the defenses, outbreaks soon occurred.

The next paper was entitled "Preventive Inoculation in Experimental Plague Pneumonia," by Professor G. Shibuyama. The author gave the history of a number of cases which had been inoculated in the recent Mongolian plague campaign, but the results were either negative or wholly unsatisfactory.

Fourth Day.

The first paper read was entitled "Researches Into the Supraepitrochlear Gland in Cases of Undiagnosed and Denied Syphilis," by Dr. Lannelange.

The second paper was entitled "The Care of the Eyesight in the Tropics," by Dr. C. Montagu Hartson. The title of this paper was somewhat misleading, in that the author dealt almost exclusively with the treatment of trachoma and other inflammations of the eye which are not necessarily associated any more with the tropics than they are with the temperate zone.

The next paper was entitled "Some Remarks on the Subject of Vesical Calculi in South China, with a Report of More Than One Thousand Cases," by Dr. J. M. Swan. In this the author related the history of a series of vesical calculi, and stated that the mortality in 1013 cases had been .076 per cent. He pointed out, however, that many of the patients in China only entered a hospital after they were in a hopeless condition. Death frequently resulted from cardiac and renal causes. Perineal section was, in his experience, the operation of choice. The largest stone extracted weighed 11½ ounces. The total weight of the calculi was 77 pounds.

The next paper, "Carbon Dioxide Snow—Its Use in Private Practice in the Tropics," was by Dr. Gregory P. Jordan. In this were given a series of instances in which this snow had been used with success in the removal of moles, warts, nevi, and other skin affections. He also reported the most excellent success in the treatment of trachoma, and stated that an ordinary case might be cured in from a few weeks to a few months, and that complete cessation of the discharge and cicatrization of the lesions invariably resulted. He gave a demonstration of the manner in which the snow was employed. The carbon dioxide is confined in a large steel cylinder, and the gas permitted to

escape into a small, round container of suitable size, which is well wrapped in gauze. The snow which forms in the container can then be readily moulded into pencils, plates, or other forms convenient for the area in which it is to be used.

The next paper was entitled "The Result of the Past Two Years' Work in the Study of Tropical Sunlight," by Dr. Paul C. Freer. The author has an exhaustive digest of the extensive observations which had been made in connection with the actinic and other rays in various parts of the world. Reports were obtained from as far south as Australia and as far north as Libau, in Russia, and numerous observations at Manila, Assouan, Cairo, Alexandria, and Washington were recorded. From these the author concluded that the actinic ray is of no more significance in the health of man in the tropics than it is in the temperate zone, and that its action depends largely upon the meteorological conditions—that is to say, upon the state of cloudiness and vapor which obscures the rays of the sun. In addition to the experiments which were reported last year by Aaron, at the meeting of the Philippine Islands Medical Association, Dr. Freer related an experiment that had been made with white rabbits, black rabbits and gray rabbits, at Baguio, which is at an elevation of 5,000 feet, and has a night temperature which frequently falls to 50°, or even lower. Upon these rabbits being exposed to the sun it was found that the black rabbits were much less able to resist the effects of the rays than were the white rabbits. For instance, the black rabbits died as the result of 30 minutes' exposure, and the white rabbits were not affected by the exposure, and were later exposed for the period of an hour or more without damage, while black rabbits again succumbed. He also reported a series of skin examinations which had been made on Americans and Filipinos. These showed that sweat glands were more numerous per square inch in the Filipino than in the American, and were much more evenly distributed throughout the Filipino's body. He also stated that further experiments, made in different latitudes with regard to ionization showed that the inferences drawn from the paper which he had read two years ago had not been justified, and that, apparently, no great difference existed between this electrical phenomenon in Washington and the same phenomenon in Manila. The author reviewed his researches into the chemical and physical properties of light in connection with the recent experiments which have been made regarding the color of materials for clothing for use in the tropics, and concluded that the ideal costume for the tropics would be one in which man would use no other protection against the sun than an umbrella.

Demineralized Food and Cancer. H. Packard.
Delayed Total Absorption of a Traumatic Cataract after Settlement with an Accident Insurance Company. D. Coggin.

The General Practitioner.—A. Jacobi states that while one should continue to admire the specialist, one should learn to revere the general practitioner. In twenty-five years the latter will recover the place of honor which was his fifty years ago. Alongside of his other work he will help to build characters and souls. He will then be a doctor that will not mount on a bank, as was customary for mountebanks in dark centuries; but he will again be the general adviser, having learned from the laboratory men and the specialists who are the modern handmaids of practical medicine; knowing the history of his trusting friends and taking an interest in their wholeness and wholesomeness—the chum of the old people, the intimate of confiding girlhood, and the uncle and oracle of the children.

Acute Suppurative Pericarditis in Infancy.—H. Barkan and W. P. Lucas report a case of this condition in a child 16 months old. This case illustrates, (1) the occurrence of pericarditis without any symptoms attributable to the heart beyond the collapse which is a common symptom in all cases of marked infantile atrophy; (2) the occurrence of pericarditis without any physical signs that could be made out; (3) the occurrence of suppurative pericarditis without any involvement or infection of the lungs or pleura; and (4) the absence of profuse cardiac involvement, as endocarditis or myocarditis. The only processes to which this pericarditis could have been secondary were an eczema which was gradually improving, or some subacute intestinal infection which gave no definite symptoms. There may have been a primary infection of the pericardium or a subacute intestinal indigestion. The infecting organism, the streptococcus in this case, probably gained its entrance through the skin or the intestinal tract, due to the lowered resistance in these two fields; therefore this case must probably be considered a secondary infection rather than a primary.

Blood Platelets in Normal Women, in Obstetrical Patients, and in the Newborn.—M. E. Morse concludes from her investigations that in some normal women, but not in all, there is an increase in the platelets accompanying menstruation. During the latter half of pregnancy most primiparæ have a high normal or an increased platelet count, while multiparæ usually show no rise. There are no special changes in the platelets during labor or the early days of the puerperium. At the end of the first week there is an increase which does not seem to be dependent upon lactation. In eclampsia and pre-eclamptic toxemia the platelets may be high, low, or normal, and they may be greatly increased during recovery. After postpartum hemorrhages of considerable size, the platelets show a moderate rise, with a maximum occurring late in the puerperium. The platelets may be low after prolonged labors terminated by operation. In case of short uncomplicated obstetrical operations done when the patient is in good condition, the platelets follow the same curve as in a normal labor and puerperium. In uncomplicated abdominal and vaginal operations there is in some cases a transitory rise of the platelets following operation. Scopolamine-morphine, used during labor, causes no changes in the platelets. The number of platelets at birth varies greatly, being sometimes high and sometimes low. After the end of the first week, however, these differences disappear and in early infancy the platelets are numerous (350,000 to 450,000). The platelets show a marked increase in icterus neonatorum. In hemorrhagic disease of the newborn there is no diminution of the platelets at the onset, but a posthemorrhagic rise with a late maximum. In skin lesions of early infancy the platelets may be high or rather low, depending on the condition of the child.

Demineralized Food and Cancer.—H. Packard suggests that cancer is the result of a nutritional defect due to mineral starvation. Upon the basis of this theory he presents the following dietary as suitable for cancer patients: One should exclude all white flour bread, and all articles into which white flour enters, from the diet, and substitute for it bread made from whole wheat flour. Potatoes next to bread form the most important and widely used article of diet, and properly conserved in cooking

they are rich in the food salts, which are located in the peripheral portion immediately beneath the skin. Therefore, one or two baked potatoes daily are advised prepared as follows: One should discard the heart or central starchy portion and eat the peripheral portions rich in mineral ingredients. The common way of cooking potatoes, by paring raw, soaking in cold water for an hour or two, and then boiling, dissolves out and leads out about 50 per cent. of the food salts. One should encourage the eating freely of well-cooked fresh vegetables, apples raw or cooked in any way, and fresh ripe fruits. Meats and fish may be used moderately according to inclination, bearing in mind that these probably make no difference one way or the other in the development or growth of cancer.

The Dowd Phosphatic Index in Relation to Disease of the Eye. J. C. Clemesha.

Diseases of the Pancreas.—J. B. Deaver states that his experience with these diseases comprises twenty-two acute and one hundred and thirty chronic cases. In the causation of pancreatitis both systemic and local factors have to be considered. From the viewpoint of surgery the local factors are the more important, and the chief of these is direct infection. The damming back of active pancreatic secretion into the interstitial substance of the gland is likely to result in hemorrhagic pancreatitis. About 50 per cent. of all cases of pancreatitis are associated with demonstrable disease of the gall-bladder or common duct. In the majority of instances the infective agent in pancreatitis is carried by way of the lymphatics tributary to the pancreas. Acute pancreatitis is subdivided into the hemorrhagic, suppurative, and gangrenous forms, which represent successive stages of the same process. There is no pathognomonic sign or set of symptoms of acute pancreatitis. One may with great probability infer its presence when an individual, usually an adult male in previously good health, is suddenly stricken with agonizing pain in the upper abdomen, associated with persistent vomiting of a biliary character, obstinate constipation with epigastric swelling and tenderness, and collapse; usually there are also subnormal temperature, a dusky pallor, slow pulse gradually rising, increasing general distention, all of which if unchecked lead up to a fatal termination, usually in a few days, though at times weeks may elapse or recovery ensue. The diagnosis of chronic pancreatitis is more difficult than that of the acute form. The leading and most constant symptom is pain, which varies from dull discomfort or ache to sharp lancinating or colicky pain quite like gallstone colic. Slightly less frequent than pain is the history of nausea or vomiting or both. A third important symptom is jaundice. Impairment of the pancreatic function results in loss of weight. The bowels are constipated. The physical examination rarely affords much positive information and is of more value in excluding other conditions. The Cammidge reaction, even the improved or "C" reaction, does not render any assistance. Treatment is both medical and surgical; medical in mild cases, to be continued if improvement results or symptoms are at least arrested; surgical, if medical treatment fails to relieve the symptoms. Mayo Robson was the pioneer in showing that free drainage of the biliary tract, and, through this outlet, drainage also of the pancreatic ducts, would in many instances enable the pancreas to cast off the infection and resume its normal function. This is, in a nutshell, the principle of the treatment.

Progress in Sanitary and Moral Prophylaxis.—P. A. Morrow states that some of the most significant signs of progress in this field are (1) the change in the spirit and practice of the medical profession in sharing its knowledge with the public—the break with the policy of silence and concealment; (2) the change in the attitude of the public toward the sex problem; and (3) the revolution, in pedagogic and social sentiment regarding the question of the introduction of sex teaching in schools and colleges, as well as in the home.

Preparation and Use of Thrombokinase.—L. W. Strong states that the essential feature of Batelli's method of extracting this body from the tissues is the precipitation of the aqueous extract by acetic acid, neutralizing by sodium bicarbonate, sterilizing with alcohol, and evaporating in vacuo at 37° C. The idea that the tissue juices might furnish a body which would hasten clotting, and that this might be of more service than fresh blood serum in the control of hemorrhage, led the writer to follow the method of Batelli. Thrombokinase has been used clinically with success by many operators in nose and throat work as a means of checking hemorrhage. It has also been found of service in sporadic and hereditary hemophilia.

Preventive Surgery.—J. C. Bloodgood states that one cannot hope for any better results from surgical intervention unless the methods of diagnosis now used by the minority come into general use. The general practitioner should be a better diagnostician, but the facilities for these methods are out of the reach of the large mass of the profession at the present time practising medicine far from large centers and well-equipped hospitals. Important as these methods are, however, they are not absolutely essential in the great majority of cases for the recognition of most surgical diseases in their most favorable period for surgical treatment. The average practitioner has had experience, however, with but few surgical lesions, and the author thinks that if the surgeon really desires to get his cases at an earlier and more favorable period he should study his records and present this investigation to his medical colleagues. Surgery should be resorted to earlier than is the practice at the present time. Gastric ulcer precedes the development of gastric cancer. The surgery of gastric ulcer and cancer, especially of ulcer, is by no means settled to-day, but the technique is far ahead of the diagnosis. The symptoms of cancer of the colon are also reviewed, and the author believes that this condition should

be earlier recognized in a larger number of cases. At present the patient who suffers from obstruction bringing about surgical intervention is fortunate. In this case there are almost 80 per cent. of cures of those who survive the operation itself. It is the insidious cases which should be recognized early without the aid of this complication. Cancer of the colon is a most favorable type of cancer and the technique is well established and has a minimal danger. Graves' disease in its later stages is successfully treated only by surgery. There is no doubt that cases in the early stages may recover with proper medical treatment, but a surgical operation at this stage would be perfectly safe, and it is suggested that this disease can be treated surgically in its least dangerous period, even if occasionally it may not be absolutely necessary.

Habit-Movements in Mental Defectives.—L. P. Clark and C. E. Atwood have found that in mental defectives tics, in the neurological sense of the term, are very rare, while peculiar habit-movements are very frequent. Habit-movement is the frequent or constant repetition of uncalled-for and exaggerated movements, devoid of convulsive element, but from which the patient seems to derive pleasure or satisfaction. All the habit-movements noted bear some relation to or suggest a sexual libido and often lead up to or replace the masturbatic act. Analysis of these acts permit of their being grouped in three regions of the body, which the authors refer to as "erogenous zones," a term used by Freud to signify an organ or part the stimulation of which bestows on the impulse the sexual character. The regions distinguished are that of the lower trunk embracing the genital and anal zones, the face, and the hands. The movements mostly observed in young idiots were finger or rag-sucking and pelvic rocking or swaying. All these have been repeatedly observed in neurotic children in whom they are repressed and cease in a short time, while in idiots and defectives incapable of normal education or diversions they persist and become aggravated.

Administration of Antimeningitic Serum.—A. Sophian concludes from his observations that the old method of administering serum is inaccurate and sometimes dangerous. Blood-pressure change is a very accurate guide to the quantity of serum that can be safely injected, frequently also indicating the quantity of cerebrospinal fluid that can be withdrawn. The average dose of serum as controlled by blood-pressure is smaller than by the old method. Following an injection of serum, controlled by blood-pressure, the after-effects are usually much less severe.

Meningitis Simulating Uremia.—G. W. McCaskey states that sporadic cases of this disease are probably more frequent than is commonly supposed, and while some may have been wrongly so reported many other cases have probably passed unrecognized. There should be no doubt in the diagnosis. Both the epidemic and sporadic cases are due to the same organism. It is just as reasonable to suppose that sporadic cases of this infection may occur as those of typhoid, scarlatina, etc. The failure of the sporadic case to propagate others is as easily explained in one case as in the other. With a low virulence of the organism a special or exaggerated susceptibility may be needed for it to produce its specific effect. The author presents a history of a case in which a provisional diagnosis of uremic convulsions has been made. The patient had the cardiovascular conditions incidental to long-continued high blood-pressure. The urine was scanty and heavily loaded with albumin, and with these the diagnosis of uremic convulsions or coma seemed justified. The comparative suddenness of the onset in ordinary health, the high temperature and return of completely normal renal function were sufficient grounds for suspicion. Examination of the spinal fluid and of the blood revealed the typical diplococcus of meningitis.

Chloride Excretion in Alcoholic Cirrhosis.—A. C. Burnham reports the history of a case of alcoholic cirrhosis of the liver, in which there was but slight involvement of the kidneys as confirmed by autopsy, and in which the following points were noted: There was a constant and continuous decrease in the elimination of water and chlorides. Diuretics had only a slight and transitory effect on elimination. A dose of 10 grams of salt was followed by a retention of water, and a corresponding increase of body weight. The retention of salt appears, in some cases, to be the primary process. A diet of low salt content may be of service in prolonging the ascitic stage of cirrhosis, thus allowing time for the desired collateral circulation.

Pneumonia in Tuberculosis.—J. W. Pettit states that one is in the habit of regarding afebrile cases of tuberculosis as most dangerous and acute exacerbations as unfavorable. Ordinarily this view is correct, but not rarely the acute pneumonic process set up by a mixed infection heals rather than disintegrates. This is not the acute tuberculous pneumonia due to the turbercle bacillus alone, but rather the acute pneumonia due to other germs, superimposed on chronic ulcerative tuberculosis. This, if not too severe, the author is inclined to consider as favorable and he regards the prognosis after such an attack as good. A plausible explanation of the phenomenon is that the intercurrent pneumonia causes an accumulation of leucocytes in the lung, which not only overcomes the pneumonic infection, but acts on the tuberculous infection also. It is similar to the effect that has been repeatedly noted of the beneficial effect of erysipelas on chronic tuberlulous ulcers. If an accumulation of leucocytes could be induced artificially in a tuberculous focus by the use of some positive chemotactic substance—not necessarily bacterial—it might be of benefit in hastening the cure of the tuberculous process.

Derangements of the Knee following Strains and Blows. A. E. Barker.
Hypersensitiveness: the Parallelism in the Phenomena of Hypersensitiveness and Certain Clinical Manifestations of Obscure Nature. H. Batty Shaw.
The Bed Isolation of Cases of Infectious Diseases. C. Rundle and A. H. G. Burton.

Paratyphoid Fever and Meat Poisoning.—F. A. Bainbridge defines paratyphoid fever as a disease which clinically resembles, and is often indistinguishable from, typhoid fever, and which is caused either by *Bacillus paratyphosus A* or by *Bacillus paratyphosus B;* the latent period varies generally from eight to eighteen days, and the usual mode of infection is by human carrier cases. Meat poisoning is a disease of which the characteristic symptom is acute gastroenteritis of comparatively brief duration, and which is caused in a very considerable proportion of cases by either *Bacillus enteritidis* (Gaertner) or *Bacillus suipestifer:* the latent period is short, rarely exceeding forty-eight hours, and the usual source of infection is contaminated meat. Paratyphoid fever in Europe is much more frequently caused by *Bacillus paratyphosus B* than by *Bacillus paratyphosus A*. The course of a typical case of paratyphoid A fever closely resembles that of mild typhoid fever. The incubation period varies from ten to eighteen days, and is usually about fifteen days. The onset of the illness is gradual, the patient complaining of severe frontal headache and pains in the back and limbs. Bronchitis and sore throat are not infrequent. The temperature rises in a step-like fashion, reaching its maximum by the fifth or seventh day; it falls gradually and becomes normal at the end of the second week. In severe cases the temperature may remain raised for three or four weeks. In contrast with mild typhoid fever the pulse is rapid and is quite often as much as 110; the frequency of the pulse in paratyphoid fever does not necessarily indicate that the attack

is a severe one. The abdomen is slightly distended, the spleen is enlarged, and constipation is the rule. The typical rash is often present and other forms of rash (*e.g.*, purpuric or morbilliform—are occasionally seen. Relapses are not infrequent and phlebitis, cholecystitis, and anæmia are not uncommon complications. Intestinal hemorrhage and perforation have been observed, but are rare. Although practically every symptom and complication of typhoid fever also occur in paratyphoid A fever the majority of the cases are of a mild character; sometimes the illness is so slight that it may be readily overlooked, and ambulant cases have been met with. The mortality is less than 2 per cent.

Derangements of the Knee Following Strains and Blows.—A. E. Barker describes the following conditions that may result from strains of or blows upon the knee-joint: partial separation of the semilunar cartilage; enlarged synovial membrane; rheumatoid arthritis of the knee; typical displacement of the internal meniscus; chips of articular cartilage free in the joint; rupture of the lateral ligaments; rupture of crucial and probably of lateral ligaments; fracture of tibial spine; effusion of blood into the joint; and hysterical affections of the knee.

Hypersensitiveness.—H. Batty Shaw advances the view that in clinical medicine certain unexplained phenomena may after all be due to the mechanism of hypersensitiveness. It may be that asthma, epileptic seizures (for example, those found to follow upon infantile hemiplegia), the coma met with in cirrhosis of the liver and granular kidney, "uremic" palsies, "uremic" fits, "uremic" diarrhea and vomiting, various forms of local or general edema occurring independently of albuminuria and kidney disease or other ordinarily accepted cause, the convulsive seizures of general paralysis, and eclamptic convulsions may all be examples of hypersensitiveness. It is possible that an eclamptic woman is really suffering from an absorption of amniotic fluid. Recurrent edema of the lungs independent of an infection, even emphysema itself not dependent upon excessive muscular exercise, recurrent hemiplegia and monoplegia, which are entirely recovered from, and which can be traced to no known cause, the excitation and depression which are such marked features in insanity, pruritis, and the many unexplained skin manifestations such as urticaria, also may be due to hypersensitiveness. The proteins responsible for the production of these phenomena may be derived from the individual so afflicted.

Bed Isolation of Cases of Infectious Disease.—C. Rundle and A. H. G. Burton record their experience with this procedure during the past two years at the City Hospital, Fazakerley, Liverpool. The total number of cases of infectious disease treated was 473. There were only two instances of ward contagion. It is admitted that facilities for the spread of disease by aerial infection are obviously greater under the system of bed isolation than under cubicle isolation; in fact, a total breakdown of the system of bed isolation might be expected if aerial infection were of common occurrence. In the light, however, of the very satisfactory results obtained by this latter system, as compared with those of cubicle isolation, it is argued that the danger of spread of infection in a hospital ward by means of aerial infection is to be disregarded for practical purposes. It would appear that the practice of rigorous asepsis on surgical lines has a value equal to or greater than of any of the accepted methods of separation by artificial barrier.

Münchener medizinische Wochenschrift.

March 12, 1912.

Is Uremia an Acidosis?—Straub and Schlayer state that thus far we know nothing of the nature of uremia. Among the many theories concerning the latter the acidosis doctrine goes back to 1888, when von Jaksch noted that uremic blood showed diminished alkalescence. Owing to technical shortcomings, no advance has been made in this direction until recently, when after Haldane and others began to report results in the estimation of carbonic acid tension in the lungs it was found that the latter would serve as a measure of acidosis. One of the writers (Straub) has published results of work of this character in diabetic acidosis. Thus far the two authors have tested eight uremic patients for carbonic acid tension. In these cases the latter was always below the lowest normal values, and each case showed some individuality. The tension increased as the uremic phenomena disappeared under treatment. In case six a value was obtained by chance before uremia developed and was found to be normal, although the patient had chronic nephritis due to lead poisoning. When uremia developed later (it was evidently precipitated by an attack of erysipelas) the tension fell below normal. In one fatal case the tension was as low as that of the severest diabetic acidosis. The question arises, "is this acidosis in any way due to inanition?" This is readily answerable in the negative. Nutrition was good, patient had been eating well, and had not vomited. Naturally an inanition factor might conceivably be present in some cases. Acetone and acetoacetic acid were absent in all cases. The authors will continue these researches.

The Eucalyptus Treatment of Scarlatina.—Koerber has been testing Milne's treatment at the Hamburg-Eppendorf Hospital. The English pediatrist had been using eucalyptus in scarlatina for a quarter century. The author divided his material so that a certain number of patients were treated by Milne's method, while the remainder were managed in the usual way. In addition to inunctions with eucalyptus oil, Milne recommends swabbing the throat every two hours with 10 per cent. carbolic acid. The treatment is intended incidentally to prevent the spread of the disease to others, including return cases. This point was especially investigated and apparently with an unfavorable result, as the frequency of return cases was not lessened, but, in fact, slightly increased. In regard to mortality, this under the customary treatment was but 2.56 per cent., and Milne's method did not lower this figure much since 2 per cent. of fatalities occurred. On the other hand, the method fulfilled a third claim, viz., that it prevents complications. This was strikingly true for such as endocarditis and nephritis, although arthropathies were present even in excess percentage. The treatment did not shorten the average duration of the disease. The author's results compare well with those most recently published in Great Britain as far as discouraging the claim that eucalyptus antagonizes the infectious element of the disease *in toto*. It is not denied that it is a good treatment, but may not be superior to the measures already in vogue. The future must determine this point.

Failure of Transfusion in Pernicious Anemia.—Bennecke saw much pernicious anemia in the Jena medical clinic during 1909-10—a dozen cases during six or eight months. The disease appears to be on the increase, not only in the author's vicinity, but elsewhere. Five cases were subjected to transfusion, four by the intravenous and one by the subcutaneous route. Defibrinated blood only was used. It was necessary to take blood for one transfusion from a healthy subject who had recovered some time before from typhoid and whose blood still contained agglutinins. No lives were absolutely saved. Some may have been prolonged, but one may have been shortened. The blood finds showed no decided improvement. The typhoid agglutinins disappeared from the recipient's blood.

The Albumin Reaction of the Sputum in Pertussis.—D. Paulian found this reaction to be positive in almost all cases of pertussis in which it was looked for, although none of these cases gave any evidences of tuberculosis.—*Revista stiuntzelor medica.*

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

TABLE OF HEIGHTS AND WEIGHTS FOR MEN.—A proper relation of weight with height and age should be required when selecting a certain group of risks, otherwise the mortality in that group will be too high in spite of the utmost care which may have been exercised in excluding other unfavorable elements. The companies have adopted approximately uniform tables for determining this relation, and as so much emphasis is directed to the subject the examiner ought to have some knowledge of its fundamental principles instead of harboring, possibly, the belief that it is merely a mass of arbitrary rulings. In the earliest tables, compiled in 1836, one weight and one height is given for each age, and these are supposed to be the average height and weight for that age. They are imperfect but still agree fairly well with our present standard and served as a starting point. In 1840 Hutchinson published a table of heights and weights based upon certain data gathered in England and which purports to represent the standard weight for each height at the age of 30. Compared with the present standard the weights in this table are too light for the shorter and too heavy for the taller heights. Other tables have been constructed with more or less consideration given to the influence of age, but the number of individuals observed was too small for authentic results. Finally, in 1897, Dr. George R. Shepherd offered some accurate and definite conclusions to the Association of Life Insurance Medical Directors in the form of a table of heights and weights for each quinquennium of age from 15 to 69, based upon an observation of 74,162 accepted male applicants for life insurance in the United States and Canada. The weights and heights include the clothing and shoes, so that the conditions are the same as those under which the applicants present themselves to the medical examiners. The table seemed so complete and accurate that it was adopted by the leading life insurance companies and, with occasional slight modifications made in accordance with individual opinions, is still in use.

TABLE OF HEIGHTS AND WEIGHTS FOR WOMEN.—The weights of women were roughly estimated formerly by assuming that they were 6 to 9 pounds less than men at the age of 25, and that this difference gradually diminished until it practically disappeared after the age of 45 or 50. As authentic figures were not available, this crude and unsatisfactory method was the one commonly resorted to until a few years ago. A table, based on a sufficiently large number of entrants to be convincing, was presented to the Association of Life Insurance Medical Directors in 1908 by Dr. Faneuil S. Weisse. This compilation was based on the study of the heights and weights of 59,525 insured women in the United States and Canada, and supplied a long-needed standard for use in estimating female risks.

TABLE OF HEIGHTS AND WEIGHTS FOR WOMEN

Heights	15–19	20–24	25–29	30–34	35–39	40–44	45–49	50–54	55–59	60–64

10″	144	147	151	155	159	163	167	170	170	169

By comparing this table to that prepared for men, it will be seen that there is a tendency for women to increase more rapidly in weight from age 20 to age 50 than for men. This period of more rapid increase corresponds to the reproductive period of women's lives, which, taken in connection with their more sedentary lives, would appear to be a reasonable explanation of the difference of the weight curves of the two sexes. As a matter of fact, it has been generally assumed by those interested in the influence of the bearing of children upon a woman's relative weight, that more overweights are found among women who have borne children than among those who have not.

MAXIMUM AND MINIMUM WEIGHTS.—Having established a satisfactory average of heights and weights, it remained to determine how far the individual may deviate from this standard before entering the class of overweights or underweights. As the maximum and minimum weights of men and women do not correspond with each other they must be considered separately.

Mortality.—The term "mortality" appears frequently in articles dealing with life insurance and an explanation should be inserted before going further. It means the ratio of actual deaths to expected deaths. The actuaries have compiled a standard mortality table from the combined experience of many companies by means of which the number of deaths in a given group of individuals may be calculated. If the group of individuals shows 1,000 actual deaths and 2,000 expected deaths, the mortality is 50 per cent.; if there are 2,000 actual deaths and 1,000 expected deaths the mortality is 200 per cent. The best interests of the companies calls for a mortality well under 100 per cent.

Men.—It has been assumed, in a general way, after going over much data, that a man becomes a moderate overweight when his weight is more than 20 per cent. above the standard for his age, and an excessive overweight when it is more than 30 per cent. above. Dr. Brandreth Symonds studied a large number of cases, however, and concluded that the effect of overweight is peculiarly influenced by two factors, the amount of overweight and the age of the individual. This is illustrated in the following table in which the first column stands for the age period, the second for the mortality in moderate overweights, the third for the mortality in excessive overweights:

Age	Moderate Overweights	Excessive Overweights
15 to 28	80%	88%
29 to 42	105%	121%
43 to 56	133%	162%
57 to 70	125%	156%

The deduction from this table is that 20 per cent. overweight in a person below 29 is not an impairment, or at least a mild one, but that the mortality increases with advancing age, so that an excess of 33 per cent. at age 22 is almost equal to 20 per cent. at age 45. On this basis the maximum weights are indicated as the same for all ages in the following table.

In the case of underweights, the influence of age is reversed as the younger ages are the ones most affected, while the older ages are but slightly disturbed. The minimum weights, therefore, are given for each age period in this compact table which will be useful to the medical examiner.

TABLE OF MAXIMUM AND MINIMUM HEIGHTS AND WEIGHTS FOR MEN

Height	Maximum for all Ages	Minimum for Different Ages			
		Age 15–24	Age 25–29	Age 30–39	Age 40 and over
5′ 0″	160	96	100	103	106
5′ 1″	163	98	101	104	108
5′ 2″	166	99	102	105	110

6′ 3″	240	145	152	157	161

Women.—Overweight and underweight women, measured by their own standard, show practically the same mortality as in the case of men. On account of the different course pursued by the increasing weight, already referred to, as compared to that of men, the maximum as well as the minimum weights for each age period are included in the following table. It will be observed that young women, as in the case of men, are not classed as overweights unless they are 33 per cent. or more above the standard, but that they are only allowed 20 per cent. at the age of 45 or over.

The minimum at 20 per cent. below standard holds good for all ages.

TABLE OF MAXIMUM AND MINIMUM HEIGHTS AND WEIGHTS FOR WOMEN

Height	Age 15–19	Age 20–24	Age 25–29	Age 30–34	Age 35–39	Age 40–44	Age 45–49	Age 50 and over

Occupation, Social Condition, and Heart Disease.—A. Grotjahn states that diseases of the heart and blood-vessels occurring in workmen are more apt to be found in those engaged in tasks requiring prolonged and severe exertion, for example, in coppersmiths, laborers, porters, etc. Even though the strain on the cardiovascular system does not produce any conspicuous pathological manifestations, nevertheless it may predispose or contribute to a premature breakdown. The statistics of the Imperial Insurance Office for the period from 1896 to 1897 show that, of 1,000 cases of illness, disease of the heart and arteries occurred in 71 men and 103 women. In spite of the greater morbidity from cardiovascular disease which is found in the lower classes of society, the mortality from this cause is greater among the upper classes. This is a fact confirmed not only by experience but also by statistics. Thus, Sörenson classified according to age-groups and social condition, among 100,000 cases of death in Denmark, those caused by cardiovascular disease, as follows:

Age in Years	Copenhagen				Rural Districts			
	Men		Women		Men		Women	
	Lower Class	Two Upper Classes	Lower Class	Two Upper Classes	Lower Class	Two Upper Classes	Lower Class	Two Upper Classes
20–35	20	30	20	30	20	30	30	40
35–45	80	50	80	70	50	50	60	50
45–55	190	120	140	90	90	160	90	80
55–65	280	350	310	160	160	220	220	180
65–75	470	550	700	450	310	680	390	470

Similarly, S. Rosenfeld found that in Vienna of every 1,000 of the population there died from circulatory diseases among the well-to-do classes 1.55 and 1.64, as against 1.31 and 1.16 among the poorer classes. This greater mortality from cardiovascular disease among the upper classes is explained by the fact that the latter attain a riper age, and are therefore more apt to succumb to such diseases.—"Soziale Pathologie."

Surgical Diseases of the Nose and of Its Accessory Sinuses in Relation to Life Insurance.—F. Röpke states that a subject of great importance is the attitude of life insurance companies with reference to applicants who have been operated upon for empyema of the nasal accessory sinuses. Before these applicants can be accepted the suppuration must have ceased. An exception may be made in the case of operations on the maxillary sinus in which complete success has not been attained, and in which there may be a discharge of pus into the nasal cavities or through an opening made in the canine fossa or in the alveolar process. In such cases there is neither directly nor indirectly any danger to life, provided that the disease process is strictly localized, which is to be expected from the topography of the superior maxilla. The conditions are, however, different in the case of the other accessory sinuses, whose walls are in direct apposition to the cranial cavity. If, in spite of operation, suppuration should continue in these sinuses, there is danger of the process invading the interior of the cranium, even though in some cases this danger may be remote. At any rate, the acceptance of these risks must be postponed until the suppuration has entirely disappeared, which in the majority of cases would follow appropriate operative treatment. Previous operations for nasal polypi, provided there has been no complicating sinus suppuration that still continues, and previous operations on the soft parts of the nose and on the septum for the relief of nasal obstruction do not militate against the acceptance of a risk. Applicants who have been operated upon for a lupous or tuberculous process in the nose must be rejected, even though at the time of examination apparent healing has taken place. The same applies in malignant disease.—"Handbuch der spezielle Chirurgie des Ohres und der oberen Luftwege."

Book Reviews.

A Pocket Atlas and Text-Book of the Fundus Oculi with Note and Drawing Book. Text by G. Lindsay Johnson, M.A., M.D., F.R.C.S., Fellow of the Royal Society of Italy (Modena); Fellow der Gesellschaft Naturforschender Freunde, Berlin; Fellow of the American Society of Ophthalmology and Laryngology; Late Ophthalmic Surgeon West End Hospital for Nervous Diseases; Consulting Ophthalmic Surgeon Western General Dispensary, etc. With drawings from life by Arthur W. Head, F.Z.S. Illustrator of "The Mammalian Eye." Frost's Atlas of the Fundus Oculi," etc. Price $2.50 net. Chicago: F. A. Hardy & Company, 1912.

The work of Johnson and Head is comprised in a compact little volume of 203 pages with 54 plates in color, and accompanying the volume is a small sketchbook for the purpose of recording the conditions of the fundus oculi as they come before the surgeon. In the text the methods of ophthalmoscopy and skiascopy are described, then follows a chapter on the anatomy of the chorioid, ciliary body and retina. The rest of the text is devoted to a description of the normal and pathological appearances that may be observed by the ophthalmoscope. The colored prints of the fundus are beautifully drawn and are very true to nature. The work is practical and would be a valuable addition to the working library of every one who is engaged in the treatment of diseases of the eye.

Hautveränderungen bei Erkrankungen der Leber. Von Sanit.-rat Dr. S. Jessner, Königsberg i. Dr. Price 60 Pfennigs. Wurzburg: Curt Kabitzsch, 1912.

In an essay of twenty pages Dr. Jessner presents the various skin changes, from jaundice to xanthoma, frequently observed in the diseases of the liver. There is nothing original in this study, but the known facts are well presented.

Ärztliche Fortbildungkurse der freien Organisation für die medizinischen Kurse an der K. K. Universität, Wien. Postgraduate medical work under the patronage of the free organization for medical courses at the University of Vienna. Berlin and Vienna: Urban und Schwarzenberg; New York: Rebman & Company, 1912.

The above contains a full description of the opportunities for doing postgraduate work at the medical faculty of Vienna University with all necessary details as to lectures, including free lectures by professors, and so forth. It should prove a useful vade-mecum for the foreigner in Vienna desirous of doing medical postgraduate work.

Honan's Handbook to Medical Europe. A Ready Reference Book to the Universities, Hospitals, Clinics, Laboratories and General Medical Work of the Principal Cities of Europe. By James Henry Honan, M.D., Rush Medical College (University of Chicago), Imperial Frederick William University of Berlin, etc. With maps of Berlin, Edinburgh, London, and Paris. Price $1.50 net. Philadelphia: P. Blakiston's Son & Co., 1912.

The object of this book, as stated in the preface, is to give a concise, comprehensive outline of the medical work of Europe, as a guide to English-speaking physicians who go abroad for post-graduate work and as a book of reference for all who are interested in medical work in other lands. It appears to fulfill this object in a satisfactory manner.

Fourth Report of the Wellcome Tropical Research Laboratories at the Gordon Memorial College, Khartoum. Volume B. General Science. Andrew Balfour, M.D., B.Sc., F.R.C.P. (Edin.), D.P.H. (Camb.), Director. Price, cloth, $4.50 net. Published for Department of Education, Sudan Government, Khartoum, by Ballière, Tindall and Cox, 8 Henrietta Street, Covent Garden, London. Depot for the United States, Toga Publishing Co., New York City.

The first part of the Fourth Report of the Wellcome Tropical Research Laboratories at the Gordon Memorial College, Khartoum, contained the record of the purely medical aspects of the work of research. The present volume deals with general science. Dr. Andrew Balfour with his able band of coadjutors writes these reports, and as may be imagined from the scientific and literary attainments of all concerned, and from the nature of the country to which they refer, the book teems with interest and information. The first chapters contain the report of the Chemical Section compiled by Dr. William Beam and is instructive in a high degree. The chapter on experiments on gum production in Kordopan by Mr. E. S. Edie is of practical as well as of scientific value. Perhaps the most engrossing and certainly the most attractive part of the volume is the Report of the Entomological Section by Harold H. King. The account of mosquitos collected by King during three months spent on the White Nile in 1909 tells of the discovery of five new species and a new sub-species. Descriptions are given of blood-sucking insects other than mosquitos met with, a sufficiently lengthy list. Mr. Fred V. Theobald describes a new genus and two new species of culicidæ from the Sudan. Mr. A. L. Butler, F.Z.S., M.B.O.U., Superintendent, Sudan Game Preservation Department, writes on the finches and weaver birds of the Sudan. These birds do much damage to the grain crops. They are excellently described by Butler. The chapter on scorpions and allied annulated spiders of the Sudan is contributed by Professor Franz Werner of the University of Vienna. Sir Thomas R. Fraser, M.D., F.R.S., the well-known authority on snake poisoning, writes a note on the Sudan spitting-snake. Ancient Gold Mining in the Sudan is discussed by Mr. Stanley C. Dunn, Sudan government geologist. Dr. C. E. Seligmann writes on the cult of Nyakang and the Divine Kings of the Shillak, while Captain R. G. Anderson, R.A.M.C., describes some tribal customs in their relation to medicine and morals of the Nyam-nyam and Gour people inhabiting the Eastern Bahr-El-Ghazal. These people believe in evil spirits and their remedies for disease are weird in the extreme. The last chapter of the book is devoted to the consideration of some municipal engineering problems in the tropics with special reference to Khartoum City and is contributed by Messrs. W. H. McLean and G. E. Hunt. It would seem from a perusal of these pages that Khartoum, from the standpoints of sanitation, water supply, and housing, need not fear comparison with many Western cities. The complete volume, in addition to being filled with valuable information and well written, is a splendid example of the printer's art. It is excellently bound and printed and contains throughout beautiful illustrations in colors and black and white and several maps. Dr. Balfour and his fellow workers in the Sudan are doing good work. It is a boon to the human race that this book should be published in behalf of future generations.

O roli selezinki pri Bolyezni Banti i drugikh splenomegalicheskikh zabolyvaniakh (The Rôle of the Spleen in Banti's Disease and Other Splenomegalic Affections). By A. Strukoff. Moscow, 1911.

In Russia the title of "doctor of medicine" is conferred upon a physician only after he has been in practice or in scientific work for several years and has written and defended a dissertation on some medical subject. The volume before us is a dissertation of this nature.

Dr. Strukoff has collected and abstracted all the published cases of anemia splenica (type Banti-Griesinger), splenomegalia (type Gaucher), anema splenica infantum, and finally of Banti's disease proper. These cases are exceedingly well brought together in four large tables that give the reader all necessary information about them.

The second part of the book is devoted to an experimental study of the behavior of the spleen in animals poisoned by various hemolytic substances, and to an attempt to explain the pathogenesis of Banti's disease by the results of these experiments. A complete bibliography is appended. The book is very valuable for any student of splenic disease. Being written, however, in that little known language, Russian, it makes one see the advantage that existed in the past, when Latin was the universal language of science, or may exist in the future, when some one tongue (even Esperanto if need must be) may become intelligible to every educated man.

Diseases of the Genitourinary Organs Considered from a Medical and Surgical Standpoint, Including a Description of Gonorrhea in the Female and Conditions Peculiar to the Female Urinary Organs. By Edward L. Keyes, Jr., M.D., Ph.D., Professor of Genitourinary Surgery, New York University and Bellevue Hospital Medical School; Surgeon to St. Vincent's Hospital. New York and London: D. Appleton and Company, 1912.

The most important change made in the text of this edition is the introduction of a special chapter dealing with salvarsan. The unquestioned value of this preparation in the treatment of syphilis, its mode of administration, dosage, after-effects, and toxicology are briefly discussed. The author prefers the intravenous method of administration in the smaller doses repeated, *i. e.*, 2 or 3 decigrams not oftener than once a week or less often than every two weeks for from 4 to 6 times. He advocates the use of mercury following salvarsan, since experience thus far has shown that we may only temporarily check the activity of the disease with Ehrlich's preparation if used alone.

Society Reports.

NEW YORK ACADEMY OF MEDICINE

Stated Meeting March 21, 1912.

THE PRESIDENT, DR. WILLIAM M. POLK, IN THE CHAIR

THIS meeting was held under the auspices of the Section on Dermatology, and was devoted to the consideration of diseases of the skin in relation to internal disorders.

Gastrointestinal Dermatoses.—Dr. UDO J. WILE read this paper, the title of which he said should properly include all the diseases in which the cutaneous and alimentary systems, from the mouth to the anus, were coincidently involved, but he proposed to limit his remarks to those disorders of the skin and gastrointestinal tract which resulted from the ingestion and absorption of certain foodstuffs and drugs. In cases of food or drug idiosyncrasy the symptoms which manifested themselves on the skin following the ingestion of such substances were erythema and urticaria; in rarer instances more violent eruptions, bullous, hemorrhagic, or purpuric in character were met with. So also in the alimentary canal, the symptoms varied with the degree of susceptibility, from mild cramps to violent gastroenteritis, with vomiting, diarrhea, and, more rarely, hemorrhage. In the past ignorance of the nature of these manifestations had been cloaked under the vague terms autointoxication, toxic rashes, and idiosyncrasy. But now, by the application of the principles of immunity to this problem, investigation had been turned into the right channels and they were in a fair way toward the solution of the subject of idiosyncrasy. Experimental studies in this connection were based upon the work of Richet, v. Pirquet, and Schick, and the hypothesis of Wolff-Eisner on anaphylaxis. By anaphylaxis they understood a condition of the organism due to a preliminary sensitization by a small dose of protein substance, followed by a condition of hypersusceptibility to repeated doses of this protein. That Wolff-Eisner's hypothesis was along the lines of correct reasoning was shown by the work of Carl Bruck, which appeared in 1909. From his experiments Bruck concluded that hog serum and crab meat contained substances to which rabbits and guinea pigs showed hypersusceptibility. The question arose as to whether such phenomena produced in animals by the injection of alien proteins could be applicable to the idiosyncrasy of human individuals following the ingestion of these same substances. The fact that Rosenau and Anderson had been able to sensitize guinea pigs to bovine and horse serum by feeding them at first on beef and horse meat lent color to this possibility. Bruck, in an experiment on a young man who, owing to an indiscretion in diet of eating too much sausage made of pig meat, had been unable to eat pork in any form, as the slightest amount gave rise to violent itching and urticaria, had been able to show this definitely in the following experiment: He injected 10 c.c. of this patient's inactivated serum into guinea pigs and twenty-four hours afterward they were injected intraperitoneally with 5 c.c. of inactivated hog's serum. Of two animals so treated both became anaphylactic and one died. Control animals remained entirely normal. From this experiment Bruck concluded that the peculiar idiosyncrasy to pork in this patient depended upon an experimentally proved hypersusceptibility to hog protein. The writer reviewed the "Case of Food Allergy, Idiosyncrasy to Eggs, Oatmeal, and Almonds," reported before the Section on Pediatrics of the New York Academy of Medicine on February 8, and described in the report of that section in the MEDICAL RECORD of March 2. This was a typical case of marked idiosyncrasy to egg, following an initial sensitization of the organism. Of special interest was the method of treatment by which Schloss was able to immunize his patient so that at the present time eggs were tolerated and complete immunity to oatmeal established, as well as a lessened susceptibility to almonds. In considering drug idiosyncrasy they were confronted by the fact that they were here dealing with non-protein substances and substances which were more or less toxic to the normal individual. Recent experiments, however, tended to show that drug idiosyncrasy was closely analogous at least, if not identical in nature, with idiosyncrasy to protein in foodstuffs. There were but few drugs in the Pharmacopeia to which certain individuals had not been shown to exhibit an idiosyncrasy. Certain ones stood out, however, by reason of the frequency with which intolerance to them was encountered; such were the iodides, bromide compounds, iodoform, quinine, copaiba, mercury, and the members of the coal-tar series. Up to the present time iodide of potash, antipyrine, bromide of potash, and mercury had been studied experimentally. The writer reviewed the work of Bruck, Klausner, Cruveillier and Maniloff in experimenting with drug idiosyncrasy and concluded that the evidence in the case of iodine, bromine, antipyrine and quinine pointed to a phenomenon closely allied to anaphylaxis as the logical explanation for the train of symptoms following their ingestion by hypersusceptible individuals. It seemed safe to assume that further experimentation would show other drug idiosyncrasies to be readily explainable on the same basis.

Diseases of the Skin in Relation to Hepatic and Renal Disorders.—Dr. L. DUNCAN BULKLEY read this paper, in which he said that the relation between derangements of the liver action and diseases of the skin had been but little observed and studied and there were relatively few cutaneous disorders which had been definitely traced to and clearly shown to be definitely dependent upon the former; there were, however, enough of them and also enough indirect indications of an intimate connection between the two to make a study of the relationship interesting and profitable. After calling attention to the importance of the liver as a factor in connection with metabolism and the consequent significance of derangements of its action in relation to many disorders and diseases of various organs and structures of the body, the writer stated that perhaps the most striking and definite skin affection connected with liver derangement was found in the pruritus which accompanied jaundice. Murchison had found that while it was absent in many cases of jaundice, he had frequently known itchiness of the skin to be a source of extreme distress to patients with hepatic derangements unaccompanied by jaundice. Xanthoma in its multiple form had been shown pretty clearly by Hutchinson and others to be also associated with biliary disturbance in a considerable proportion of cases at least: while another form of the disease, exhibiting more inflammatory lesions, had so far been connected with faulty glycogenic action of the liver as to have received the name of xanthoma diabeticorum. Boils and carbuncles were also associated with glycosuria and this was universally recognized as an effective predisposing cause of the condition of the skin in which pus cocci found a satisfactory soil for growth. Disturbance of the urea formation function of the liver played no inconsiderable part in connection with several diseases of the skin, though evidence of this was clinical and had not thus far been supported by actual chemical or laboratory tests. Urticaria was also an eruption which had been traced by Murchison and others to functional derangement of the liver, and finally pigmentation of the skin, varying all the way from a dirty sallow complexion to well-defined chloasma, resulted from hepatic derangement in a certain number of cases as the results of treatment often showed conclusively. The exact manner in which disorder of the liver affected the skin had never been demonstrated, but it could be readily understood that a toxemia from imperfect liver action might irritate the nerves and cells of the skin, and in conjunction with external causes or independently could give rise to pruritic sensations and alterations of structure, even as it could cause changes in the joints in gout and deforming arthritis. The connection between diseases of the skin and renal derangements was a more satisfactory field of observation and research because of the ease with which the urinary excretion could be secured and analyzed and the relations noted between its varying composition and the condition of different eruptions. The urine was a most perfect exponent of the catabolism and anabolism of the system, and too much stress could not be laid upon the importance of its repeated and complete volumetric analysis in very many cases of skin disease. By it they might learn daily much which could not otherwise be ascertained in regard to the manner in which the nutritive processes of the body were carried out and the character of the blood which induced the eruption on the skin. This was strikingly illustrated in two cases of dermatitis herpetiformis recorded by Hardouin. Making a daily analysis of the urine of twenty-four hours over a period of nearly six months, he found that in one case on eight occasions, at pretty regular intervals, there was a fresh outbreak of the eruption after a period of diminished excretion of urea. In the second case the onset of the attack repeatedly coincided with the lowest point of urea excretion. This relationship had been confirmed by other observers. In the study of the relation of skin diseases to renal derangements it was not albumin and casts or glycosuria which were sought for, but the volumetric changes in the many constituents of urine which might be considered normal

were it not that it was often quite imperfect in regard to some of its elements. Insufficient and defective function of the kidneys, not necessarily actual disease, played a most important part in connection with many diseases and were of special significance in relation to certain affections of the skin. Not only was it important that the chemical ingredients of the urine should be in the proportions belonging to health, but it was essential that the individual should pass them in sufficient quantity. The actual volumetric acidity of the urine often afforded the greatest aid in determining the exact state of the patient as to the alkalinity of the blood. Practically the reaction of this high acidity was continually observed in connection with many diseases of the skin and eruptions would often be seen to be red and congested and the itching increased when there was high acidity and would be relieved when the urinary acidity was reduced. The daily excretion of urea afforded, as all knew, a valuable indication of the nitrogenous metabolism of the system which often had an important bearing on certain diseases of the skin, notably psoriasis. Indican in excess in the urine was being recognized more and more as a valuable indication of putrefactive changes occurring in proteids, mainly in the large intestine. Many cases of urticaria arose from intestinal putrefaction and careful examination of the urine as to indican would often afford intelligent indications for the treatment; the same was more or less true regarding eczema, acne, and perhaps other affections of the skin. The occurrence of urates in the urine and the appearance of crystals of uric acid were always of more or less significance in many diseases of the skin which were frequently aggravated when they appeared in the urine; they afforded a good indication of the so-called gouty state often associated with them. Clinically the finding of crystals of oxylate of lime in the urine did not commonly indicate gastorintestinal disturbances or those of the liver which were found to be of significance in connection with certain diseases of the skin. The quantitative estimation of the chlorides excreted was sometimes of value in connection with the treatment of certain cutaneous affections, as indicating the state or condition of the nutrition at large and the character of the food taken. The amount of phosphates in the urine might also afford considerable information of value along the line of treatment of many patients with diseases of the skin associated with or dependent upon neurotic elements. Continued increased elimination would often indicate a waste of nervous tissue and energy, which must be met by proper measures. In chronic diseases in which the nutrition of the body suffered the excretion of phosphates might be far below the normal, and this condition should be met by proper measures if the best results were to be obtained in treating the condition of the skin. The sulphates might often prove to be a good indicator of the proper metabolism of proteid substances. Mention had been made of a number of more or less acute and some chronic cutaneous affections in regard to which functional disturbances of the liver and kidney action had been observed to be of etiological moment, and it therefore seemed probable that careful study would demonstrate that the same was more or less true of other eruptions which had not thus far been investigated in this direction and possibly that in every case in which skin was diseased with few exceptions there might be some metabolic errors which might be evidenced in the urine when sufficient time, patience and skill were employed to detect him. Skin diseases as a class were notoriously rebellious and it behooved dermatology to look away from the purely local etiology and therapeutics and to seek for underlying causes, which were often dependent upon a defective metabolism which was indicated by hepatic and renal disorders.

Skin Diseases in Relation to Nervous and Sexual Disorders.—Dr. S. POLLITZER read this paper. He said that the skin was an organ of such great complexity of structure and function that it needed no elaborate demonstration to show that in one way or another the nervous system was involved in the lesions underlying most dermatoses. The effects of the nervous diseases were manifested through the sensory nerves and those of the sympathetic system especially the vasomotor nerves. In addition there were trophic disturbances of the skin in consequence of central nerve disease of which the exact mode of occurrence was still undetermined—the clinicians, as a rule, assuming the existence of special trophic nerves, the physiologists explaining these trophic lesions as of vascular or neurovascular origin. The subject might be divided into three groups: 1. Skin diseases whose connection with the nervous system was established by their constant association with definite lesions of the central nervous system. 2. Skin diseases which occurred in connection with great organic diseases of the central nervous system. 3. Skin diseases which occurred in connection with the so-called vasomotor trophic neuroses and those in which the connection with the nervous system was purely hypothetical. There was only a single disease of the skin in which there was constantly present a definite anatomical lesion of the central nervous system, namely, herpes zoster. Head and Campbell had shown that zoster always implied a lesion of the spinal ganglion of the nerve of the affected area, and that this lesion was a hemorrhagic inflammation with destruction of ganglion cells and nerve fibers and the cutaneous lesion did not correspond to the region supplied by the ganglion cells, but rather to a definite spinal cord segment. However, the pathology of zoster was by no means cleared up. In addition to the cases of idiopathic zoster the disease occurred symptomatically in a variety of conditions; in connection with destructive lesions of the central nervous system like tabes, hemiplegia, chronic spinal meningitis, etc.; in many infectious diseases; in disorders of metabolism; in many toxemias, uremia, eclampsia, arsenic, carbon dioxide poisoning, etc. In considering the dermatoses of the great organic diseases of the central nervous system they should bear in mind that these diseases were of great chronicity and it was possible for many things to happen to the patient during his long illness. There was, indeed, no lesion of the skin which constantly accompanied the organic diseases of the central nervous system and none which could be explained as depending directly on the central lesion. The skin diseases of the vasomotor trophic neuroses constituted a group of great clinical and pathological interest. The condition known as erythromelalgia was not a disease but rather a symptom complex on the basis of organic or functional disorders of the central nervous system or of the peripheral nerves. In one case in which there were symptoms of Raynaud's disease the post-mortem examination disclosed extensive atrophy of the gray matter of the cervical and dorsal cord involving the intermedio-lateral tract and the basal cells of the posterior horns. In other cases no lesion of the central nervous system could be found; in still others the sole changes were severe arteriosclerosis of the vessels and thickening of the nerves of the affected limb. As to erythromelalgia, while vasomotor disturbances played an important rôle in the disease there was no evidence at all of involvement of the central nervous system. In Raynaud's disease the probabilities seemed to favor the view that this was an affection of the vascular rather than of the nervous system. The question of the nervous origin of various inflammatory dematoses had during the past decade greatly occupied dermatologists. The weight of evidence was decidedly on the side of the hematogenous origin of the angioneurotic dematoses. The rôle of the vasomotor nerves in the production of skin disease was nevertheless one of great importance. The effects of long continued hyperemia were manifested in a diminished resistance of the affected area and skin diseases might develop secondary to such a locus minoris resistentiæ. Through the vasomotor nerves the emotions might enter into the causation of skin diseases. Pigmentary and trophic changes in the nails and hair were often cited as examples of this, but it must be said that recent critical sifting of the evidence threw some doubt on the reality of the occurrence of these remarkable changes that were popularly supposed to take place in a few hours. Many of the lesions supposed to be due to hysteria were in reality of traumatic origin. There was still a number of dermatoses for which a connection with the central nervous system had been assumed on grounds wholly insufficient. It might be said that with the advance of knowledge the number of dermatoses to which a nervous origin might be ascribed had constantly grown less and to-day they regarded external infections and internal toxemic conditions as the principal factors in the causation of skin diseases. As to the relation of skin diseases to the sexual organs, the writer said that in men the dermatoses connected with the genital organs were of less importance and less frequent occurrence than in women; this was because the genital glands in the male were of less physiological importance as compared with those of the female and were less subject to disease. The connection between certain dermatoses and disorders of the genital organs in women lacked distinct experimental foundation, but that such a connection existed was so strong and so direct that there could be no reasonable place for doubt. The writer considered the dermatoses of puberty, menstruation, pregnancy and the climacterium, and explained the relationship between these and the various dermatoses on the basis of vasomotor and glandular changes. He said that the entire subject was one of great difficulty in the present state of our knowledge. The difficulty in the way of an

understanding of the pathological effects of altered internal secretion was increased by the enormous complexity of the chemical correlation that existed between the various organs of internal secretion, so that they were often at a loss to know whether it was a subsecretion or supersecretion of one organ or the resulting disturbance in the secretion of another that produced the disturbance in the effects clinically observed. One fact, however, seemed evident, they must give up their traditional notions of a mysterious reflex action in these cases. They were dealing with the internal secretions, with chemical substances of a definite and in most cases relatively simple chemical constitution.

Dr. Alexander Lambert said that the general practitioner often saw instances of skin diseases arising from disordered conditions in the intestinal tract and it certainly was a pleasure to him to have had the privilege of listening to Dr. Wile's paper and what he had to say in regard to anaphylaxis and drug poisons. It was very interesting to watch the sensitiveness which appeared in different people to insect bites. Some appeared to be naturally immune to the bites of all insects and some immune only to certain insects. Some only appeared to suffer from the bite of the mosquito. Those who lived where the insect was the most common appeared to be the least affected. Some were very sensitive to very small doses of opium, and to even 1/50 grain of heroin, and this peculiarity seemed to run in families. Again they did not see to-day as they did years ago the number of rashes that were caused by the giving of antipyrine when it was the fad to use this agent in the reduction of temperature; veronal had largely been abandoned because of the many rashes that resulted from its employment, even in small doses. This was a hypnotic that had to be abandoned because it produced a group of rashes that did not occur when sulphonal or trional were used. It seemed to Dr. Lambert that what was found in the urine was an expression of the state of metabolism; the kidneys were the great chemical laboratories of the body and filters of products that were brought to them. There were many substances which they got rid of; at the same time there were certain imperfectly broken down products that they were unable to get rid of. It was one of the functions of the liver to break down certain poisons or substances into their end products and these the kidneys could care for. This, however, Dr. Lambert said, was a subject about which very little was known.

Dr. Theodore C. Janeway said that it was exceedingly interesting to note to what extent dermatology had developed, yet this was purely a descriptive science. The papers read showed very clearly the pathological anatomy of skin diseases that was being investigated, and this study would certainly be very fruitful, especially in the study of the etiology and pathogenesis. For many years the dermatologists had had a fruitful field in the study of the many lesions of the skin, but it should be remembered that the etiological study of skin lesions was far more difficult than the etiological studies they dealt with in internal medicine. These lesions were far more difficult to decipher. There were so many skin lesions associated with so many different disturbances of the internal organs that one was often at a loss to explain any real relationship. If every skin lesion was as definite and clear cut as heart lesions or diseases accompanied by high blood pressures it would be different. The problems that confronted dermatologists were very difficult ones and especially that which concerned the exanthematous diseases. Anderson and Goldberger had tested the problem quite clearly and practically had solved it. Dermatological problems might be solved along the same lines they employed. The question of the soil was very striking and very important, and as in tuberculosis depended much upon the non-resistance of the bacilli in particular individuals and upon the rôle they played in determining what individual should fall a prey to the disease. This same thing applied in dermatology. In diabetic patients the skin lesions were most striking, as well as in cases of chronic nephritis where there were such great disturbances in metabolism, with retention of the products of metabolism, increase of the amount of urea in the blood and other associated conditions such as were seldom seen in other disturbances. Dr. Janeway confessed that it was very difficult for him to believe in any definite clear-cut relation between the retention of metabolic products and disturbances of the skin. In closing he called attention to the phenomena of anaphylaxis due to the use of buckwheat in the diet, and the many urticarias and many cases of hypersensitiveness which followed the use of certain spices which had been adulterated with buckwheat.

Philadelphia Neurological Society.

At a stated meeting held March 22 Drs. Jay C. Knipe and Samuel Leopold presented a communication entitled "A Case of Dyspituitarism, with Interesting Eye Symptoms." The patient was a drug clerk, seventeen years old, who, without warning, was seized with impairment of vision, first in one eye and then in the other. Examination disclosed a binasal hemianopsia, with swelling and edema of the optic papilla. There were no motor or sensory or mental symptoms, and the reflexes were unaltered. There were some increase in weight and some growth in stature, and also cyanosis of the extremities. The levulose test for carbohydrate tolerance was not made. The *x*-ray picture was not clear. The Wassermann test yielded a negative response. The genitalia appeared to be unaffected. Marked improvement took place under administration of potassium iodide. The symptoms were attributed to disease of the hypophysis, the further development of which was to be carefully looked for. Dr. John H. W. Rhein presented "A Case of Bitemporal Hemianopsia." The patient was a man, forty-two years old, with a history of several attacks of gonorrhea, but who denied syphilitic infection. He had had several convulsions at the age of eighteen. When about thirty-five years old the eyesight became bad, and examination disclosed loss of vision in both temporal fields, with degenerative changes in the optic discs. The reflexes were exaggerated. There was also marked increase in bodily weight, with diminished sexual desire, and an *x*-ray picture showed apparent increase in size of the pituitary body, with wasting of the sella turcica. Dr. Alfred Gordon presented "A Case of Progressive Muscular Atrophy with Unusual Symptoms." The patient was a woman, about forty years old, who presented wasting and weakness in the small muscles of the hands and also in the muscles of the arms and the forearms, as well as of the face and tongue, with fibrillary twitching in places. There was, in addition, characteristic foot-drop and a marked steppage gait, with abolition of the knee-jerks and absence of sensory symptoms. A positive response was obtained to the Wassermann test. It was thought the case might be one of chronic poliomyelitis, with the addition of peripheral neuritis. Dr. James Hendrie Lloyd made the "Report of a Case of Brain Tumor Associated with Cystic Formation in the Right Parietal Region," and he exhibited the specimen. The patient was a young man, about sixteen years old, who complained of pain over the right eye of paroxysmal character, with vomiting independently of food, and suggestive of migraine. Examination disclosed inflammatory changes in the optic nerve on the affected side, but there was no tenderness on palpation or percussion of the skull. The patient had no convulsions and no other motor symptoms, but was subject to attacks of somnolence or stupor, so that it was not possible satisfactorily to make tests for astereognosis. A diagnosis of tumor of the brain was made, although its situation appeared uncertain, and operation was recommended, but declined. The condition of the patient grew gradually worse and death resulted. On post-mortem examination a tumor of considerable size was found in the substance of the right cerebral hemisphere behind the Rolandic area and surrounded by a space apparently resulting from destruction of adjacent brain tissue. The opinion was expressed that surgical removal would have been readily possible. Dr. Wm. G. Spiller reported "A Case of Detachment of the Tuberosities of the Humerus from Muscular Action." The patient was a man who was seized with severe pain in the arm close to the shoulder after flinging a suitcase from the railway platform to the top step of the car platform. For some time the condition was treated on the basis of a neuritis of the brachial plexus. Examination showed that the arm could be elevated only to a horizontal level, and in an *x*-ray picture it was found that the tuberosities of the humerus had become detached from the body of the bone.

Contribution to the Study of Leucemia.—F. de Marchis states that in chronic myelocytic leucemia the opsonic index varies little from the normal as long as the patient remains in good physical condition. When the nutrition and general health fail the index is much lower than normal. There is no direct relation between the number of white blood cells and the opsonic power of the blood. Under *x*-ray treatment the opsonic index is lowered owing to the diminution in the number of phagocytic leucocytes. Even the neutrophile leucocytes can acquire a phagocytic power in leucemia.—*Le Sperimentale.*

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF OKLAHOMA.

October 10, 1911

ANATOMY.

1. Name the bones of the face.
2. Describe the shoulder joint.
3. Give origin, insertion, and nerve supply of the pectoralis major.
4. Name the cranial nerves; which one takes a part of its origin from the spinal cord?
5. Describe the formation and name the branches of the lumbar plexus.
6. How may tubercle bacilli gain entrance to the lungs from the intestinal tract?
7. Describe the minute structure of the lungs.
8. Locate superficial and deep palmar arches. What vessels are concerned in their formation?
9. What anatomical arrangement makes it possible to have an infection of the middle ear from a pharyngitis?
10. Describe the cul-de-sac of Douglas.

PHYSIOLOGY.

1. Tell about the heart as follows: (*a*) structure, (*b*) nerve supply, (*c*) position, (*d*) trace the blood from the vena cava to the aorta, naming the valves, chambers of the heart, and organs it passes through in their order.
2. State circumstances that influence secretion of glands
3. Tell about the liver as follows: (*a*) structure, (*b*) nerve supply, (*c*) blood supply, (d) function of bile
4. Where is chyme found? Describe it. What is chyle and where found?
5. Give deep origin, distribution, and function of the eleventh cranial nerve (spinal accessory).
6. What functions originate in the corpora quadrigemina? What is the effect of the removal of the anterior corpora quadrigemina?
7. Give origin and function of (*a*) ptyalin, (*b*) trypsin, (*c*) succus entericus.
8. What is the composition and office of vernix caseosa?
9. Define excretion and secretion and give example of each.

MATERIA MEDICA AND THERAPEUTICS.

1. For what is santonin used? How does it affect the urine?
2. What is an alkaloid? Name one obtained from ergot, nux vomica, colchicum, pilocarpus, ipecacuanha.
3. For what is potassium permanganate used?
4. Give the therapeutic uses for mustard
5. Give indications for the use of chloral hydrate. How is it eliminated?
6. Name and explain the use of three counter irritants.
7. Diagnose and treat apoplexy.
8. What is Graves' disease? Give diagnosis and treatment.
9. Give prophylactic treatment of diphtheria, smallpox.
10. Give symptoms of gastric ulcer.

CHEMISTRY.

1. What metallic element is constantly present in the coloring matter of the blood? What is allotropism?
2. Give the characteristics of (*a*) nephritic urine and (*b*) cystitic urine.
3. In examining a specimen of urine, how detect or show there is an excess of uric acid present?
4. What is nitric acid? How formed? Give chemical symbols, specific gravity, and properties of same.
5. What antidotes are used in cases of poisoning from (*a*) carbolic acid and (*b*) caustic alkalies?
6. What is the chemical composition of pancreatic juice?
7. What is mucin, where is it found in the body?
8. What is collodion; also what is litmus?
9. What is the chemical name and formula for iodoform?
10. Give two tests for morphine

PHYSICAL DIAGNOSIS.

1. What is physical diagnosis?
2. What is a rale?
3. Name the rales.
4. What is a murmur?
5. What is a respiratory murmur?
6. Give physical signs of last stage of lobar pneumonia
7. Give physical signs of hydrothorax
8. Give physical signs of pulmonary tuberculosis in last stage.
9. Give physical signs of chronic bronchitis.
10. Give physical signs of aortic regurgitation.

BACTERIOLOGY AND PATHOLOGY.

1. Name and describe the bacilli found in leprosy, syphilis, and tuberculosis.
2. Name the bacilli of cerebrospinal meningitis and where found.
3. Name and describe the two bacilli found in pyemia.
4. Give the pathological changes that take place in chronic peritonitis.
5. Give the morbid changes that take place in diphtheria.
6. Name the pathological changes that take place in variola.
7. Classify cysts according to origin; name and describe three kinds of cysts under each class.
8. Give the morbid anatomy of actinomycosis.
9. Divide periostitis into three classes and describe each class.
10. Give complete pathology of the appendix vermiformis and the surrounding tissues usually involved.

SURGERY.

1. What is the difference between congestion and inflammation?
2. Define septicemia and give its causes.
3. What is lupus?
4. Give the diagnosis and treatment of Pott's disease
5. How may a quart of normal salt solution be prepared at the patient's home?
6. Outline the principles of treatment for a compound dislocation.
7. Name and describe the different varieties of fractures.
8. What circumstances demand amputation of an extremity?
9. At what point is paracentesis of the thorax preferably performed?
10. Give the symptoms of gallstones in the common duct.

GYNECOLOGY.

1. Describe the blood supply of the uterus and ovaries.
2. What is salpingitis? Give etiology.
3. Discuss ventrofixation of the uterus.
4. Why does retrodisplacement of the uterus cause leucorrhea?
5. Give causes and treatment of ulcer of cervix.
6. Diagnose and treat polypi of cervix.
7. Give causes of acute vaginitis.
8. What is a tampon? What are its gynecological uses?
9. Give causes of menorrhagia.
10. Give indications for knee-chest posture in office treatment.

OBSTETRICS AND HYGIENE.

1. Differentiate between puerperal eclampsia and hysteric convulsions during labor.
2. What symptoms during labor would cause you to fear postpartum hemorrhage? What measures would you use to prevent its occurrence?
3. Describe a four months' fetus sufficiently exact to be of value in a medico legal investigation.
4. At what period of gestation is abortion most dangerous? Give reasons.
5. Name several conditions of the mother that unfit her milk to nurse the infant.
6. During pregnancy, what clinical symptoms would be most likely to cause a patient to consult you for threatening toxemia of pregnancy? How would you verify diagnosis? How would you manage the case?
7. What are the symptoms of threatened abortion?
8. What causes any one to catch cold? What hygienic means should be employed by persons prone to catch cold?
9. How long does a diphtheria patient remain infective? How may it be proved that the infected period has ceased?
10. Name six efficient disinfectants and indicate the application to different purposes.

MEDICAL JURISPRUDENCE AND TOXICOLOGY.

1. How would you treat a case of morphine poisoning?
2. In a case of death by poison, what organs would you select for chemical examination, and how would you prepare them for the chemist?
3. What is melancholia?
4. Give some of the causes of death from heat, other than burns and scalds.
5. Give the technique of medicolegal post-mortem examination.
6. Give some of the conditions simulating death.
7. Give some of the most common causes of organic dementia

8. How would you diagnose and treat a case of delirium tremens?

9. Give some of the symptoms of lead poisoning and the treatment.

10. Give the effect of poisoning by acetanilide and the treatment.

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF THE STATE OF OKLAHOMA.

October 10, 1911.

ANATOMY.

1. *Bones of the face.* Two nasals, two superior maxillary bones, two lacrymals, two malars, two palates, two inferior turbinates, vomer, and inferior maxillary bone.

2. See Cunningham's "Anatomy" (1909), page 276; or Gray's "Anatomy" (1910), page 301.

3. PECTORALIS MAJOR. *Origin:* Anterior surface of inner half of clavicle, lateral half of anterior surface of sternum as far as seventh costal cartilage, cartilage of true ribs, and aponeurosis of external oblique of abdomen. *Insertion:* Outer edge of bicipital ridge of humerus. *Nerve supply:* External and internal anterior thoracic nerves.

4. *The names of the cranial nerves* are: (1) Olfactory. (2) Optic. (3) Motor oculi. (4) Trochlear or pathetic. (5) Trifacial. (6) Abducens. (7) Facial. (8) Auditory. (9) Glossopharyngeal. (10) Pneumogastric or Vagus. (11) Spinal accessory. (12) Hypoglossal.

Of these the *spinal accessory* takes a part of its origin from the spinal cord.

5. See Cunningham's "Anatomy" (1909), page 641; or Gray's "Anatomy" (1910), page 1047.

6. From the intestinal tract the tubercle bacilli gain access to the peritoneum and mesenteric lymph nodes, thence to the thoracic lymphatics, and thence to the lungs.

7. See Cunningham's "Anatomy" (1909), page 910; or Gray's "Anatomy" (1910), page 1196.

8. The *superficial palmar arch* is formed by the ulnar artery, and is completed by the ulnar artery anastomosing with a branch of the radial (superficial volar or princeps pollicis). It gives off the four digital branches.

The surface marking is a line drawn transversely across the palm from a point where the web of the thumb joins the palm.

The *deep palmar arch* is formed by the radial artery, and is completed by the radial artery anastomosing with a deep branch of the ulnar. Its branches are the palmar interosseous, perforating, and palmar recurrent arteries.

The surface marking is a line drawn transversely across the palm, one-half inch nearer the wrist than the superficial arch.

9. Infection of the middle ear from a pharyngitis is possible by extension of the inflammation from the pharynx, along the Eustachian tube, to the middle ear.

10. See Cunningham's "Anatomy" (1909), pages 1090, 1100, and 1189; or Gray's "Anatomy" (1910), pages 1256 and 1409.

PHYSIOLOGY.

1. HEART. *Structure:* See Cunningham's "Anatomy" (1909), page 791; or Gray's "Anatomy" (1910), page 565. *Nerve supply:* Vagus, sympathetic cardiac plexuses, and intrinsic cardiac ganglia. *Position:* In the thoracic cavity, obliquely behind the middle part of the sternum, and adjacent costal cartilages; about one-third is to the right of the median line and about two-thirds to the left. *Course of blood:* From vena cava into right auricle, through the tricuspid valve into the right ventricle, through the pulmonary semilunar valve into the pulmonary artery, thence into capillaries in the lungs, thence into pulmonary veins, thence into left auricle, through mitral valve into left ventricle, and through the aortic semilunar valve into the aorta.

2. *Circumstances that influence the secretion of glands:* (1) The nervous system; and (2) the amount of blood which passes through the gland.

3. LIVER. *Structure:* See Cunningham's "Anatomy" (1909), page 1121; or Gray's "Anatomy" (1910), page 1329. *Nerve supply:* Left vagus and sympathetic. *Blood supply:* Hepatic artery, (portal vein), and hepatic veins. *Function of bile* is: (1) To assist in the emulsification and saponification of fats; (2) to aid in the absorption of fats; (3) to stimulate the cells of the intestine to increased secretory activity, and so promote peristalsis, and at the same time tend to keep the feces moist; (4) to eliminate waste products of metabolism, such as lecithin and cholesterin; (5) it has a slight action in converting starch into sugar; (6) it neutralizes the acid chyme from the stomach and thus inhibits peptic digestion; (7) it has a very feeble antiseptic action.

4. *Chyme* is the food at the end of gastric digestion as it passes into the duodenum. It is a thick, grayish, acid fluid and consists of proteids, proteoses, peptones, fats, salts, and undigested matter. *Chyle* is the lymph which comes from the small intestine during the period of digestion.

5. SPINAL ACCESSORY NERVE. *Deep origin.* The medullary portion arises from the spinal accessory nucleus in the lower half of the floor of the fourth ventricle; the spinal portion arises in an elongated nucleus on the external surface of the anterior cornua of the spinal cord (as far down as the fifth cervical vertebra). *Distribution:* After emerging from the cranial cavity the nerve soon separates into two branches: (1) An *internal* or *anastomotic* branch, consisting chiefly of filaments coming from the medulla oblongata. It soon enters the trunk of the vagus, from which fibers pass to the muscles of the pharynx, to the muscles of the larynx through the inferior laryngeal nerve, and to the heart according to most authorities. (2) An *external* branch, consisting chiefly of the accessory fibers from the spinal cord.

It is distributed to the sternocleidomastoid and trapezius muscles.

Function: The transmission of nerve impulses from the cells from which they take their origin to the muscles to which they are distributed. They therefore excite to action some of the muscles of deglutition, the muscles which regulate the tension of the vocal bands during phonation, and the muscles which control the respiratory movements associated with sustained or prolonged muscle efforts; the fibers also convey nerve impulses which exert an inhibitory influence on the heart; it is the motor nerve to the trapezius and sternomastoid. (From Brubaker's *Physiology.*)

6. *The Corpora Quadrigemina.*—"The anterior tubercles of the corpora quadrigemina, together with the external geniculate bodies, form part of the primary centers of vision. The anterior tubercles, however, have to do chiefly with reflex movements of the pupil and the ciliary muscles. The posterior tubercles of the corpora quadrigemina and the internal geniculate body are connected with the auditory nerve, and have to do with reflex movements associated with hearing and space sensations. They also appear to receive some fibers from the cerebellum; their injury or disease produces some disturbances in equilibrium and possibly in hearing. Owing to the fact that the nuclei of the third nerves and the red nuclei lie beneath the corpora quadrigemina, lesions of these latter produce irritations and paralyses of the third nerve, disturbances in equilibrium and forced movements. Lesions in this neighborhood sometimes cause somnolent and stuporous states." (Dana's *Nervous Diseases.*)

7. *Ptyalin* is found in the saliva; it changes starches into dextrin and sugar. *Trypsin* is made in the cells of the pancreas; it changes proteids into proteoses and peptones in an alkaline medium. *Succus entericus* is made in Lieberkuhn's crypts of the intestine; it has a slight action on carbohydrates, turning starches into sugar, and sugar into dextrose and levulose; it acts also on proteids, splitting up proteoses, petones, and polypeptids into amino-acids.

8. VERNIX CASEOSA. *Composition:* Chiefly fat and epithelial cells. *Function:* Protection of the fetus, preservation of its skin from the action of the amniotic liquid.

9. *Secretions* are materials separated from the blood by glandular cells, and which serve some further purpose in the animal economy; as milk, gastric juice.

Excretions are materials separated from the blood by cell activity, and discharged from the body, and which are harmful if retained; as urine.

MATERIA MEDICA AND THERAPEUTICS.

1. *Santonin* is used as an anthelmintic for round worm and thread worm. It colors the urine a greenish-yellow.

2. An *alkaloid* is a nitrogenous, basic, organic substance, alkaline in reaction, and capable of uniting with acids to form salts in the same way that ammonia does. An *alkaloid:* of ergot, is cornutine; of nux vomica, strychnine; of colchicum, colchicine; of pilocarpus, pilocarpine; of ipecacuanha, emetine.

3. *Potassium permaganate* is used as an antiseptic, disinfectant and deodorant; it is an emmenagogue, and so is used in amenorrhea; it is used as a lotion for wounds, ulcers, abscesses, leucorrhea, and as an antidote in morphine or opium poisoning.

4. *Mustard* is used (in form of a paste) as a counter-irritant; as a cardiac and respiratory stimulant; in rheumatism, neuralgia, inflammations; also in amenorrhea.

5. *Chloral hydrate is indicated in* Insomnia not due to pain, whooping cough, tetanus, strychnine poisoning; also locally, as a counterirritant. It is *eliminated* by the kidneys and skin.

6. *Three counterirritants:* Mustard, cantharides, and croton oil. *Mustard* is a rubefacient, and produces a hyperemia of the skin. *Cantharides* is a vesicant and acts more vigorously than a rubefacient, producing blisters in addition to the hyperemia. *Croton oil* is a pustulant, and besides causing hyperemia and blisters it acts on the sweat glands and produces pustules.

9. See French's "Practice of Medicine" (1910), pages 194 and 309; or Osler's "Practice of Medicine" (1909), pages 123, 207, and 209.

8. See French's "Practice of Medicine" (1910), page 557; or Osler's "Practice of Medicine" (1909), page 473.

CHEMISTRY.

1. *Iron* is the metallic element constantly present in the coloring matter of the blood.

Allotropism. Some elements (as phosphorus and carbon) exist in two or more forms, in which the chemical relations remain unaltered, but the physical properties vary; these different conditions of the same element are said to be allotropic.

2. *In acute diffuse nephritis:* "The urine is greatly diminished in amount (4 or 5 ounces in 24 hours), or is even totally suppressed. It is smoky, blackish, or of a chocolate color. The specific gravity is high. Albumin is found in large amount, and the heavy deposit contains abundant red corpuscles, blood, hyaline and epithelial tube casts. The total urea is lessened."

In *chronic diffuse nephritis:* "The quantity of urine is diminished, it is cloudy from urates, the specific gravity may be high in the early, but is low in the later, stages. Albumin is abundant, sometimes more so than in any other disease. The heavy sediment contains large numbers of nearly all the varieties of tube casts, hyaline, epithelial, granular, and fatty. The latter are especially characteristic. Occasional red corpuscles, many leucocytes, and numbers of degenerated epithelial cells are also found. The amount of urea is decreased." In *chronic interstitial nephritis:* "The urine is increased in quantity, light yellow, clear, with a persistently low specific gravity. Albumin is scanty, occurring in traces and is sometimes absent. A few narrow hyaline casts are almost constantly found in the very small deposit. Cellular elements are as a rule no more abundant than in normal urine. Polyuria, persistent low specific gravity, and the presence of a few hyaline casts constitute the urinary signs of this disease. Albumin may or may not be present in small quantity."

In *acute cystitis:* "The urine is acid and contains blood, pus, albumin, and epithelium. In *chronic cystitis* the urine is turbid, alkaline, and ammoniacal. It contains a considerable amount of viscid pus, albumin, much epithelium, crystals of triple phosphates, and numerous bacteria (*Coli communis*, staphylococcus, streptococcus). Occasionally blood is present." (Butler's *Diagnostics of Internal Medicine.*)

3. *Excess of uric acid* can be shown by the centrifuge method, as follows: "The *centrifuge method* of estimating requires that the phosphates be first separated by placing 10 c.c. of urine in the percentage tube with about 1 gm. of sodium carbonate and 1 to 2 c.c. of ammonium hydrate. The phosphate precipitate is thrown down by rotation, and the clear urine poured off into another tube. To this is added 2 c.c. of ammonium hydrate and 2 c.c. of a 5 per cent. solution of silver nitrate (to which ammonium hydrate has been added until the first precipitate clears up); and the translucent precipitate of silver urate is separated by rotation. Having poured off the clear liquid, the precipitate of silver urate is washed free of chloride by mixing it with at least 5 c.c. of ammonium hydrate. The mixture is then well rotated until the precipitate is reduced to its least bulk. For 1 c.c. of this precipitate the uric acid is read off as 0.001176 gm. in 10 c.c. of urine. To get percentage this product is again multiplied by 10." (Holland's *Medical Chemistry.*)

4. Nitric acid is the chief nitrogen acid; it is a strong mineral acid, and is made by the decomposition of an alkaline nitrate by strong sulphuric acid:

$$2NaNO_3 + H_2SO_4 = Na_2SO_4 + 2HNO_3.$$

Its formula is HNO_3; specific gravity, from 1.4 to 1.5; *Properties:* It is a colorless liquid, with a strong acid taste and reaction; when exposed to air and light it is decomposed into N_2O_4, H_2O, and O. It is a strong oxidizing agent; with metals it forms salts called nitrates.

5. *Antidotes for carbolic acid:* Sodium sulphate, alcohol; *for caustic alkalies:* Vinegar, or weak acetic acid.

6. *Pancreatic juice is composed of:* Water, enzymes (trypsin, amylopsin, steapsin, and a milk curdling ferment), leucin, tyrosin, xanthin, soaps, sodium chloride, potassium chloride, some carbonates, and phosphates (of sodium, calcium, and magnesium).

7. *Mucins* are glycoproteids, found in the secretions of mucous membranes and mucous glands, saliva, bile, mucus of nose and vagina, umbilical cord and also in the urine.

8. *Collodion* is a substance made by dissolving soluble gun cotton (pyroxylon) in ether and alcohol.

Litmus is a blue pigment obtained from Rocella tinctoria, a lichen; it is used for determining the reaction of certain substances.

9. The chemical name for iodoform is tri-iodomethane; its formula is CHI_3.

10. *Two tests for morphine:* (1) Solution of neutral ferric chloride (Fe_2Cl_6) gives a blue color with morphine. (2) nitric acid colors morphine first orange, then yellow.

PHYSICAL DIAGNOSIS.

1. *Physical diagnosis* is a diagnosis made by means of physical or objective signs (such as auscultation, palpation, etc.), without regard to subjective symptoms (such as vertigo, pain, etc.).

2. *A râle* is an adventitious sound produced in the air cells or in the bronchial tubes.

3. The râles are: Dry, moist, sibilant, sonorous, crepitant, subcrepitant, crackling, bubbling, gurgling, mucous, ringing, metallic.

4. *A murmur* is a sound produced by the flow of a fluid (liquid or gas) along a tube.

5. *A respiratory murmur* is the sound heard from the lungs of a healthy adult.

6. See French's "Practice of Medicine" (1010), page 150; or Osler's "Practice of Medicine" (1909), page 175.

7. See French's "Practice of Medicine" (1910), pages 718 and 708; or Osler's "Practice of Medicine" (1909), page 646.

8. See French's "Practice of Medicine" (1910), page 375; or Osler's "Practice of Medicine" (1909), page 320.

9. See French's "Practice of Medicine" (1910), page 668; or Osler's "Practice of Medicine" (1909), page 605.

10. See French's "Practice of Medicine" (1910), page 600; or Osler's "Practice of Medicine" (1909), page 800.

BACTERIOLOGY AND PATHOLOGY.

1. *Leprosy:* The bacillus of leprosy is very much like the tubercle bacillus; it is a long and slender rod, about 6 mikrons in length, slightly curved; it is non-motile, non-flagellate, has no spores, is acid-resisting, gram positive, and stains (generally) in the same way as the tubercle bacillus. It has not yet been cultivated on artificial media, and (so far) is pathogenic only for man.

Syphilis: The germ of syphilis is the *Treponema pallidum*, also called the *Spirochæta pallida*. It is a slender spirillum, with regular turns, the curves varying in number from three or four to twelve or even twenty; it is about 4 to 20 mikrons long, actively motile, with a fine flagellum at each pole; it is flexible, hard to stain, and has not been cultivated on artificial media. How it divides is not known. It stains best with Giemsa's eosin solution and azur.

Tuberculosis: The tubercle bacillus is rod shaped, is from 1½ to 3½ mikrons in length and about one-third to one-half a mikron in breadth, is a strict parasite, is not motile, and has no flagella. It is slightly curved, does not form spores, is not liquefying, and nonchromogenic, is aërobic; it resists acids; it grows well on blood serum, glycerin agar-agar, glycerin and gelatin; stains well by Ehrlich's, Ziehl-Nielsen's, or Gabbett's method; it is Gram positive.

2. See French's "Practice of Medicine" (1910), page 139; or Osler's "Practice of Medicine" (1909), page 159.

3. The *Streptococcus pyogenes* is a micrococcus, of spherical shape, and arranged in chains of about thirty or forty cocci (in liquid media), but the chains are much shorter in solid media. Each coccus is about one-half to two mikrons in diameter. It is not motile, does not form spores, does not liquefy gelatin, and stains readily with the ordinary anilin dyes, and by Gram's method.

The *Staphylococcus pyogenes aureus* is a small round cell which appears in clusters like a bunch of grapes; its diameter is about 0.8 to 1.0 mikron; it is facultative anaërobic, has no flagella, is not motile, it stains readily with the

anilin dyes, and is not decolorized by Gram's method; it forms an orange pigment on gelatin, potatoes, and other media; it also liquefies gelatin.

5. See French's "Practice of Medicine" (1910), page 182; or Osler's "Practice of Medicine" (1909), page 198.

6. See French's "Practice of Medicine" (1910), page 330; or Osler's "Practice of Medicine" (1909), page 114.

7. See Rose and Carless' "Surgery" (1911), page 222; or Da Costa's "Surgery" (1911), page 306.

8. See French's "Practice of Medicine" (1910), page 465; or Osler's "Practice of Medicine" (1909), page 294; or Rose and Carless' "Surgery" (1911), page 181; or Da Costa's "Surgery" (1911), page 309.

9. See Rose and Carless' "Surgery" (1911), pages 500, etc.; or Da Costa's "Surgery" (1911), pages 501, etc.

10. See French's "Practice of Medicine" (1910), pages 807, etc.; or Osler's "Practice of Medicine" (1909), pages 512, etc.; or Rose and Carless' "Surgery" (1911), pages 1046, etc.; or Da Costa's "Surgery" (1911), pages 985, etc.

SURGERY.

1. *Congestion* is excess of blood in the more or less dilated blood-vessels of a part.

Inflammation is the name given to the series of changes occurring in a part as the result of some injury, provided such injury does not at once destroy the vitality of that part.

Congestion is the first stage of inflammation.

2. See Rose and Carless' "Surgery" (1911), page 84; or Da Costa's "Surgery" (1911), pages 209 and 210.

3. See Rose and Carless' "Surgery" (1911), page 401; or Da Costa's "Surgery" (1911), page 250.

4. See Rose and Carless' "Surgery" (1911), page 717; or Da Costa's "Surgery" (1911), page 862.

5. *To prepare a quart of normal salt solution:* Take a quart of water, filter it and sterilize it; then dissolve one and a half drams of table salt in it, and again boil the water.

6. See Rose and Carless' "Surgery" (1911), page 615; or Da Costa's "Surgery" (1911), page 668.

7. See Rose and Carless' "Surgery" (1911), page 467; or Da Costa's "Surgery" (1911), page 517.

8. *Conditions which justify amputation of a limb* are "Any injury, disease, or malformation rendering retention of the limb incompatible with life or comfort; avulsion of limb; compound fracture; compound dislocation; fracture with great comminution of bone; laceration of important vessels; extensive contusion; extensive laceration; gunshot injuries; aneurysm; effects of heat and cold; gangrene; extensive bone disease; tumors; elephantiasis; tetanus; snake bite; deformities." (Bickham's *Operative Surgery.*)

9. See Rose and Carless' "Surgery" (1911), page 955; or Da Costa's "Surgery" (1911), page 903.

10. See Rose and Carless' "Surgery" (1911), pages 1075 and 1076; or Da Costa's "Surgery" (1911), page 1033.

GYNECOLOGY.

1. See Cunningham's "Anatomy" (1909), pages 1102 and 1185; or Gray's "Anatomy" (1910), pages 1412 and 1493.

2. Salpingitis is inflammation of the Fallopian tube. *Causes:* Septic infection, gonorrhea, menstrual congestion, taking cold at the menstrual periods, cancer, tuberculosis.

3. *Ventrofixation* consists in fixing the uterus to the anterior abdominal wall; it is performed for displacement of the uterus, and is often more satisfactory than shortening the round ligaments. Hermann (*Students' Handbook of Gynecology*) states objections to this operation as follows: "(1) Its risk. Oversights will occur in the practice even of the most careful; but the risk is very small. (2) Adhesions within the peritoneum are sometimes absorbed. They are absorbed often enough to make stitching of peritoneum to peritoneum unsatisfactory. After abdominal section ventral hernia may first develop after the scar has held firm for twelve years; and possibly the new attachment of the uterus may also, after many years, give way. (3) The operation lifts up the uterus. If the vulval orifice is very large there may still be a protrusion of the vaginal mucous membrane. It is well, therefore, to precede ventral fixation in women past child bearing by posterior colporrhaphy. (4) It is said to cause difficulty in labor, should the patient become pregnant. It does not always do so; and in many cases reported as illustrating such difficulty, the ventral fixation was not the cause of the difficulty. Ventral fixation after colporrhaphy, if the result be permanent, relieves the patient of any necessity for the continual readjustment of a pessary, and lifts the uterus up effectually. Ventral fixation is not advised in cases in which the womb can be comfortably kept up by a pessary."

4. Retrodisplacements of the uterus are generally accompanied with interference of the circulation in the uterus, this is followed by congestion and enlargement of the body of the uterus and later on by hypertrophy of the endometrium. These conditions cause the leucorrhea.

5. Ulcer of cervix. *Causes:* Carcinoma, tuberculosis, chancre, chancroid, friction from pessaries and in prolapse of the uterus.

Treatment: Remove the cause, if possible, local treatment, as for similar conditions elsewhere; constitutional treatment, as indicated; if hypertrophy is present amputation may be necessary; in cancer, hysterectomy may be required.

6. *Polypi of cervix.* "Polypoid tumors are found growing from the mucous membrane of the cervical canal, projecting into the canal or protruding from the external os. The mucous polypus is the most usual form, and is caused by cystic degeneration of the Nabothian glands of the cervical mucous membrane. Sometimes such polypi protrude from the ostium vaginæ. Less often a papillary or warty growth is found on the mucous membrane of the cervical canal, in the neighborhood of the external os. There is usually present dilatation of the external os and cervical canal. The symptoms of cervical polypi are not characteristic. Inflammation of the cervical mucous membrane and cervical catarrh may result. There may be slight, and rarely profuse, bleeding from the external os. The bleeding may follow efforts at straining, sexual connection, long standing, or exercise. Occurring at the time of the menopause or later, this symptom would excite the suspicion of beginning cancer of the cervix.

"Pediculated polypi should be twisted or cut away. Bleeding is usually very slight. The sessile growths, like the papillomata, should be excised, the incision being carried well below the base of the tumor into the healthy tissue of the cervix. The wound may then be closed with an interrupted suture. In every case of such tumor a careful microscopical examination should be made to determine its benign or malignant character." (Penrose's *Diseases of Women.*)

7. Acute Vaginitis. *Causes:* Gonorrhea, erysipelas, diphtheria, tuberculosis, syphilis, chancre, uncleanliness, obesity, pessary or other foreign body, sexual excesses, vaginal fistulæ, diabetes or other condition with irritating urine.

8. A *tampon* is a small roll of absorbent cotton, about 2½ x 1 inches, and is inserted into the vagina either with or without some medicinal substance. Around the center of the tampon is a strong string, long enough to hang out from the vulva, and by which the tampon can be removed. The details of the mode of use will depend upon the condition for which the tampon is employed. In any case the patient's bowels should be empty, and as a rule she is placed in either the dorsal or knee-chest position. The tampons are removed after about 36 hours, and a douche is then taken. The *purposes* of a vaginal tampon are: For controlling hemorrhage, either vaginal or uterine; to exert pressure; to support the uterus; as a means of applying medication locally; and for depleting inflammatory conditions.

9. Causes of menorrhagia. *Local causes:* Uterine displacements, malignant disease, inflammations of uterus or appendages, fibroids, cystic degeneration of the cervix, subinvolution, ectopic gestation, abdominal tumors.

General causes: Hemophilia, scurvy, purpura, malaria, anemia, mitral disease, diseases of kidneys, or liver, acute infectious fevers.

10. *Knee-chest posture* is employed (in office treatment) for the replacement of a retroverted uterus, or of a prolapsed uterus or appendages; or for insertion of tampons in the vagina.

OBSTETRICS AND HYGIENE.

1. See Jellett's "Midwifery" (1910), page 619; or Hirst's "Obstetrics" (1909), page 632.

2. See Jellett's "Midwifery" (1910), pages 350 and 365; or Hirst's "Obstetrics" (1909), pages 342 and 586.

3. See Jellett's "Midwifery" (1910), page 108; or Hirst's "Obstetrics" (1909), page 85.

4. Abortion becomes more dangerous as gestation advances. In the earliest weeks the ovum may be expelled entire with little or no danger; but after the formation of membranes, decidua, and placenta, there is always a risk of part of these remaining.

5. *When maternal nursing should not be attempted.*—"(1) No mother who is the subject of tuberculosis in any form, whether latent or active, should nurse her infant; it can only hasten the progress of the disease in herself,

while at the same time it exposes the infant to the danger of infection. (2) Nursing should not be allowed where serious complications have been connected with parturition, such as severe hemorrhage, puerperal convulsions, nephritis, or puerperal septicemia. (3) If the mother is choreic or epileptic. (4) If the mother is suffering from any serious chronic disease or is very delicate, since great harm may be done to her, without any corresponding benefit to the child. (5) Where experience on two previous occasions under favorable conditions has shown her inability to nurse her child. (6) When no milk is secreted. With reference to the fourth and fifth conditions, an absolute opinion cannot always be given at the outset." (Holt's *Diseases of Infancy and Childhood.*)

6. See Jellett's "Midwifery" (1910), pages 606, 617, 619, and 620; or Hirst's "Obstetrics" (1900), pages 203, 249, and 230.

7. See Jellett's "Midwifery" (1910), page 637; or Hirst's "Obstetrics" (1900), page 276.

8. *Taking colds:* General debilitating conditions (such as exposure to cold, damp, etc.) are predisposing factors, also poor hygiene; overheated and poorly ventilated rooms; the exciting cause is probably some bacterium. To avoid taking cold, the patient should be surrounded with the best hygienic conditions (suitable clothing, avoidance of draughts, proper ventilation, exercise, bathing, etc.); he should also remove any factors that militate against good physical health.

9. See French's "Practice of Medicine" (1910), page 194; or Osler's "Practice of Medicine" (1900), pages 207 and 210.

10. See Rose and Carless' "Surgery" (1911), page 266; or Da Costa's "Surgery" (1911), pages 26 and 63.

MEDICAL JURISPRUDENCE AND TOXICOLOGY.

1. *Treatment of morphine poisoning* consists in washing out the stomach, preferably with a dilute solution of potassium permanganate; ambulatory treatment, to keep the patient awake; artificial respiration is indicated, and strong coffee should be administered by the mouth or rectum; the bladder should be emptied by the catheter. There is no antidote.

2. In case of suspected poisoning "the following portions of the cadaver should be preserved: The alimentary canal from the cardia to the middle of the rectum, *unopened*, and the contents inclosed by ligatures at the esophagus, duodenum, and lower end of gut; the liver, including the gall-bladder; one kidney; the spleen; a piece of muscular tissue from the leg; the brain, and any urine which may remain in the bladder. Any suspected food articles and any obtainable vomited matter are to be also preserved. All of these are to be placed in *clean* and *new* glass jars, closed with glass or cork covers or stoppers. Jars with metallic caps should never be used. Tapes or cords should be tied about the jar and can, to which they should be attached by sealing wax bearing impressions of a seal, in such a manner that access can be had to the interior only after breaking the seals or cutting the tapes or cords. Great care must be exercised that no sealing wax can get into the jars. Each portion should be placed in a jar by itself."—(Witthaus's *Essentials of Chemistry and Toxicology.*)

3. *Melancholia* is a variety of mental disorder, characterized by a general perversion of the mental faculties and accompanied by depression.

4. Causes of death from heat, other than burns and scalds, are: Heat exhaustion, heat collapse, thermic fever, suffocation.

5. For the details of post-mortem examination see some good text-book on Medical Jurisprudence or Pathology.

6. *Conditions Simulating Death:* Coma, epilepsy, trance, and partial asphyxia.

7. See French's "Practice of Medicine" (1910), page 1128; or Osler's "Practice of Medicine" (1900), page 896.

8. See French's "Practice of Medicine" (1910), page 986; or Osler's "Practice of Medicine" (1900), page 372.

9. The *symptoms of acute lead poisoning* are: "Metallic taste; dryness of the throat; thirst; severe colicky abdominal pains, referred particularly to the umbilical region, and relieved by pressure; pulse very feeble and slow; great prostration; constipation; urine scanty and red; violent cramps; paralysis of the lower extremities; convulsions, and tetanic spasms." The *treatment* consists in administering "magnesium sulphate, which brings about the formation of the insoluble lead sulphate, while the purgative action of the magnesia is also useful. It should be preceded by an emetic or by the use of the stomach tube."

10. POISONING BY ACETANILIDE. *Effect:* Chilliness, cold sweat; nausea; pulse is soft, slow, and feeble; respirations slow and shallow. *Treatment:* Lavage, diffusible stimulants, application of heat, coffee or strychnine, inhalation of oxygen, or saline infusion.

Medical Items.

Serodiagnosis of Typhoid Fever.—C. Gatti studied the agglutinating power of the blood serum of typhoid fever patients with respect to the paratyphoid and colon bacilli. With respect to typhoid bacilli agglutination is always positive in dilutions of 1 to 100; there is no relation between the amount of fever and the agglutination power. In dilutions below 1 to 100 typhoid serum causes the agglutination of paratyphoid and colon bacilli. The author has thus demonstrated the non-specificity of the reaction of agglutination possessed by typhoid serum with respect to other bacteria of the same species.—*Il Policlinico.*

Adrenalin in the Treatment of Asthma.—E. Tranquili has used adrenalin in the treatment of spasmodic asthma with the following results. In 24 per cent. of the cases of essential asthma it had no effect; in asthma due to renal or cardiac disease it has no appreciable value; in reflex asthma it has a favorable effect whether used locally in the nasal mucosa or administered by the stomach or rectum or hypodermically. In one case preceded by gastric symptoms when adrenalin was administered by the stomach or rectum it had an abortive action, but by hypodermic injection it had no effect. If we desire to quickly stop an attack of asthma morphine is to be preferred to adrenalin. But the latter is preferable to nitrite of amyl, though less active than inhalations of chloroform or pyridin. When asthma is accompanied by cardiac dilatation adrenalin and oxygen, together with cold applications over the heart, are effective in stopping the suffering. Regulation of the diet and the administration of iodides between the attacks favor the action of adrenalin.—*Gazzetta Medica di Roma.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended March 29, 1912:

Places.	Date	Cases.	Deaths.
CHOLERA.			
India: Bassein	Jan. 26–Feb. 3	39	32

SOME SALIENT POINTS IN THE HISTORY OF THE CAUSAL AGENT OF SYPHILIS.

By JOHN BETHUNE STEIN, M.D.,

NEW YORK.

"There is one thing among all which I affirm, it is that this disease is contagious."—C. Galinus, 1497.

DONNÉ,[1] in 1837, described a microorganism which he discovered in ulcerated syphilitic lesions of the penis and vulva and which he considered the cause of syphilis. In 1838 Ricord[2] attacked Donné's claim and the latter abandoned it in 1844, when he stated he could not invariably find the organism in the syphilitic products. This organism of Donné was a vibrio or spirillum and Donné's description of it is "an animalcule having the form of a vibrio described by Müller under the name of the Vibrio lineola." A drawing of the spirillum by Donné himself is to be found in his work, "Recherches Microscopiques sur la Nature des Mucus," Paris, 1837. It is highly probable that with the means at his command Donné did not see a spirillum so fine as that of Schaudinn's.

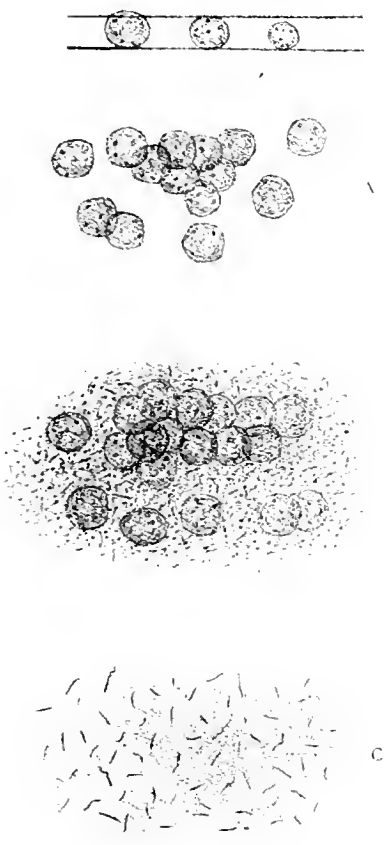

Fig. 1—A, Pus from gonorrhea. B, Pus from chancre. C, Vibrios contained in the pus from a chancre. From a plate in "Recherches Microscopiques sur la Nature des Mucus," by Dr. Alfred Donné, 1837.

Fig. 2—Dr. Alfred Donné.

Alvarez and Tavel[3] (1885) found spirilla in smegma. Berdal and Bataille[4] (1861) and Csillag[5] (1898) found the same organisms in the products of ulcerative balanoposthitis. Róna[6] of Budapest (1903-1905) found a spirillum in nine primary lesions, but he did not consider it an etiological

Fig. 3—Dr. P. Ricord.

factor in syphilis, as he found it in non-syphilitic lesions (gangrenous lesions of the genitals) in the genital smegma in both sexes, and in a case of mercurial stomatitis.

The coarse thick spirillum described by these observers is, in the opinion of such men as Rille, Metchnikoff, and Roux, identical with the organism described by Donné, and the *Spirochæta refringens* described in 1905 by Schaudinn and Hoffmann and

Fig. 4—Dr. Sigmund Lustgarten.

Fig. 5—Dr. S. Róna.

Fig. 6—Prof. T. H. Rille.

which is found about the genitals in both specific and non-specific lesions. Rille[7] believed that he had discovered in 1894 the *Treponema pallidum* of Schaudinn.

In 1884, about the time when the tubercle bacillus was discovered by Koch, Lustgarten,[8] who was working in Weigert's laboratory, observed a bacillus in gummata and chancres which in form and in the difficulty of staining resembled the tubercle bacillus. Lustgarten considered this organism as the cause of syphilis, and it has been since known as the bacillus of Lustgarten. It was found in syphilitic skin lesions and was thought to be present in other organs of syphilitics. Doutrelepont and Schutz[9] (1885), Marcuse[10] (1888), Babes[11] (1885), and others regarded the presence of this organism as valuable in the diagnosis of syphilis. Bitter[12] (1886), Alvarez and Tavel (1885), however, identified this acid resisting bacillus of Lustgarten with a saprophytic organism normal to the genital organs, the smegma bacillus. Sabourand[13] (1892) looked in vain for Lustgarten's bacillus in fifty-one sections of syphilitic lesions.

Kassowitz and Hochsinger[14] (1886) and Disse and Taguchi[15] (1887) alleged that the streptococci and diplococci were the causal agents of syphilis, without substantiating their assertions.

Since 1896, von Niessen[16] has claimed that a bacillus, discovered by him, and probably the same as that found by Joseph and Piorkowsky[17] (1902), is the cause of syphilis. This claim "he has defended against all contradictions with a tenacity and vigor little known" (A. Lefebvre).[18] He asserts that he has found his bacillus in the blood, in the great majority of cases of syphilis examined by him.

Von Niessen's bacillus is of the same genus as that of pseudodiphtheria. It is polymorphous; at times a coccus, sometimes a short thin rod, or a rod thickened at its ends, or a longer rod containing three or four granules disposed in series which are metachromatic. It grows well on gelatin serum and bouillon, but poorly on agar. He further claims that he has, by inoculating the hog and monkey with this bacillus, infected them with syphilis. But Neisser, Bärmann, and Halberstädter,[19] during the course of their recent experiments in Java, were unable to transmit syphilis to different species of monkeys, which were inoculated with cultures made by von Niessen himself.

It was at about this period in the history of the discovery of the causal agent of syphilis that the attempt was made by Klingmüller[20] and Bärmann to verify the prevailing opinion that this agent was a virus belonging to the so-called invisible microorganisms. They obtained the virus from primary lesions and condylomata, which mixed with a given quantity of normal salt solution, they triturated for one or two hours. This emulsion was then filtered through a Berkefeld filter (pressure 250 mm. of water). The filter had been previously tested with a culture of the spirilla of chicken cholera and only those filters which were impermeable for these microorganisms were employed. Klingmüller and Bärmann inoculated themselves three times with the

Fig. 7—Prof. Klingmüller.

products thus passing through the filters, not only by scratching the skin and rubbing the material in the wound, but subcutaneously. In spite of the large quantity of filtered virus used and the care that was exercised to prolong the contact, no manifestations local or general, were noted. They came to the conclusion that the microorganism of syphilis did not pass through the filter and therefore it could not be classed among the organisms called invisible.

Metchnikoff and Roux,[21] thinking that the foregoing experiment was open to some objections, as several hours were necessary to obtain the filtrate

and that the virulence of the material might be altered by the salt solution, obtained the virus from an indurated chancre of the penis and from two chancriform syphilides of a woman. This was diluted with 2 c.c. of the aqueous humor of a sheep and filtered through a 12A Berkefeld filter. This filter permits the passage of the microorganism producing peripneumonia in bovines, but prevents the passage of the vibrios living in water and those

Fig. 8—Prof. Elie Metchnikoff.

Fig. 9—E. Roux.

Fig. 10—Dr. Siegel.

of chicken cholera. The passage of the diluted virus through the filter occupied fifty minutes. A chimpanzee was inoculated with the filtered liquid by scratching the skin in the region of the supraorbital arch and thigh. At the same time another chimpanzee was inoculated in the same manner with the virulent emulsion which had not been filtered. The first animal showed no manifestations; the second animal, thirty-seven days later, showed a chancre of the supraorbital arch, followed by an adenitis of the adjacent lymph nodes, and a typical eruption. They concluded that the syphilitic virus did not pass through this Berkefeld filter, and that the microorganism of syphilis was therefore not in the class of invisible microorganisms.

It has been known for some time that a disease

Early in 1905 Siegel, a German zoologist, described a protozoon, the *Cytorrhyctes luis*, in the blood and exudates of syphilities, which he regarded as the cause of syphilis. He was supported in this claim by his collaborators, W. Schulze[24] and F. Schulze,[25] Professor of Zoology in the University of Berlin. This discovery created a sensation. The organisms discovered by Siegel had a diameter of 0.5 to 2.5 microns, appeared round, oval, and pyri-

form, and were probably blood plates or broken-down erythrocytes.

Although the claim that here at last was found the causal agent of syphilis had to be abandoned, yet, by a curious chance, Siegel's discovery of the *Cytorrhyctes luis* was indirectly the cause of, or at least furnished the occasion for, the discovery by Schaudinn of the *Treponema pallidum*.

In February, 1905, Kohler, the director of the Imperial Sanitary Bureau at Berlin, named a commission of medical men and naturalists to ascertain whether the *Cytorrhyctes luis* of Siegel was, as Siegel claimed, the cause of syphilis. The commission was composed of Hoffmann, the first assistant of Lesser, for the clinical and histological side, Neufeld and Gonder for the bacteriological, and Schaudinn

Fig. 11—Dr. Erich Hoffmann.

Fig. 12—Fritz Schaudinn.

Fig. 13—Dr. A. Buschke.

of the genitals of the horse resembling syphilis (dourine) can be transmitted in coitus and be produced by a trypanosome. It was therefore thought that possibly syphilis was caused by a protozoon. Schüller[22] (1905) claimed not only that he had discovered, in specific products, certain bodies covered with cilia having sacs filled with spores, but that he had cultivated these bodies.

for the zoological side. Schaudinn was not a physician but a protozoologist and his researches upon the coccidia, the protozoal hemoparasites, and spirilla were well recognized, and during his stay at Rovigno and Herzegovina he had made a particular study of the spirillum of relapsing fever. In his work upon the *Leukocytozoon ziemanni* he had found, in the cycle of evolution of this parasite,

stages which established a close relationship between protozoa with flagella and the spirochetes.

Schaudinn was unable to find the organism of Siegel in chancres and lesions of secondary syphilis which had been excised by Hoffmann. However, on the 3d of March, 1905, he was struck by the presence, in the fresh extravasation from a papule which was slightly eroded, of a very small motile spirocheta which was extremely difficult to

Fig. 14.—Dr. Jules Bordet.

Fig. 15.—Dr. Octave Gengou

Fig. 16.—Prof. A. v. Wassermann

study. The history of the case is the following:

A woman, aged twenty-five, presented since January 20, 1905, a painless nodule on the labium majus. On March 3, 1905, a papulosquamous eruption, general adenopathy, and an initial lesion accompanied with slight eroded papules about the vulva were seen. One of these papules was excised by Hoffmann and in the extravasation from the under surface of this papule Schaudinn saw, for the first time, the causal agent of syphilis, the *Treponema pallidum*. Schaudinn and Hoffmann then sought the *Treponema pallidum* in various syphilitic products. Their first results, finished April 10, 1905, were published April 23, 1905, from the Imperial Bureau of Sanitation of Berlin (Arbeiten aus dem Kaiserlichen Gesundheitsamte, 1905). This first contribution, entitled "A Preliminary Report on the Presence of Spirochetes in Syphilitic Products and Papillomata," contained an account of thirty observations. Their work was simply an exposure and registration of facts. They reported the discovery of two organisms, one, the *Spirochæta pallida*, which they afterward named the *Treponema pallidum*, as Ehrenberg had applied the former name to another organism, the other the *Spirochæta refringens;* but they formulated no definite conclusions as to the role these two organisms played in the pathogeny of syphilis. On May 4, 1905, they published under the title, "On the Discovery of the Spirochetes in the Lymph of Lymphnodes of Syphilitics," some facts tending to show that an intimate relationship existed between the *Treponema pallidum* and syphilis. They sought the organism in closed syphilitic lesions (the lymph ganglia in the neighborhood of the chancre) for fear it might be said that the presence of the organism in open lesions, the chancre, etc., resulted from outside contamination and was only a secondary infection. They found the treponema present and other microorganisms absent in the lymph obtained from eight lymphnodes in syphilitics in whom the duration of the disease varied from some weeks to four months. In two cases the lymph ganglia were excised and in the other six the fluid was obtained by puncture and aspiration.

Some time before the publication of his first communication, April 23, 1905, Schaudinn sent to Metchnikoff by Professor Kraus of Vienna, specimens of the organism which was soon to be considered the cause of syphilis. It was in these specimens that the organism was first seen in France. He also requested Metchnikoff to send him some smears obtained from chancres in apes which had been inoculated with syphilis in order to search them for the *Treponema pallidum*. Schaudinn, however, was unable to discover any spirilla in these smears.

The news of the still unreported discovery of the *Treponema pallidum* by Schaudinn was not a surprise to Metchnikoff, Roux, and the other experimenters at the Pasteur Institute in Paris, for Metchnikoff and Roux[26] made the following statement in their communication presenting the first results of their investigations on May 16, 1905, to the Academy of Medicine in Paris: "We know of only a single case where anyone has seen the *Spirochæta pallida* before Schaudinn and that was a single unpublished observation. Three years since Bordet and Gengou at Brussels found in a chancre a great number of spirilla, very thin, corkscrew-like in shape, and difficult to stain." They finally stained the organism with Kühne's methylene blue and Nicolle's gentian violet, and sought the organism, without success, in five chancres, in the lymphnodes, and in the papules and blood of syphilitics.

Bordet in discussing the question of the discovery of the causal agent of syphilis with the writer said that, as he and Gengou did not confirm their discovery, they consequently did not publish their results, but had sent to Metchnikoff previous to the discovery of the *Treponema pallidum* by Schaudinn a number of smears containing spirilla which they had obtained from a chancre and stained with great difficulty by means of gentian violet, and that Metchnikoff failed to find any spirilla in these specimens.

In their communication to the Academy of Medicine at Paris, May 16, 1905, Metchnikoff and Roux further state: "A few days since Bordet has sent us one of their old preparations, in which we can, not without difficulty, recognize the spirillum absolutely identical with that of the *Spirochæta pallida*."

After Metchnikoff had succeeded in inoculating chimpanzees with syphilis and was aware of the discovery of the spirillum by Bordet, he sought, with negative results, the spirillum in the syphilitic products of these anthropoids. He therefore concluded that the spirillum was not a specific cause of syphilis. Metchnikoff says later that "the bril-

liant researches inaugurated by Schaudinn have led us to renew our investigations upon the syphilitic products in apes and to modify our opinion. . . . In six syphilitic apes which we have studied we have proved the presence of the spirillum in four cases."

On May 17, 1905, Schaudinn and Hoffmann[27] presented to the Medical Society at Berlin a communication entitled "On the *Spirochæta Pallida* in Syphilis and the Difference Between This Form and Other Species Belonging to This Genus." But the history of syphilis contained so many disproved claims to the discovery of its causal agent that von Bergmann[28] ended the spirited debate, wherein the Schaudinn and Hoffmann claims were bitterly attacked at the meeting, May 17, 1905, of the Medical Society in Berlin with the remark: "On this, the discussion is closed until another causal agent of syphilis comes to claim our attention."

Fig. 17—Prof. Ernst von Bergmann.

Fig. 18—Prof. A. Neisser.

Fig. 19—Dr. Hideyo Noguchi.

The facts collected at this time, however, seemed to prove that the *Treponema pallidum* was the cause of syphilis. The organism was found in the deeper parts and on the surface of chancres, in numbers in the ganglia adjoining the chancres, to the exclusion of other microorganisms, and finally in the primary and secondary manifestations in apes which were infected with syphilis. Still the questions arose: First, as to whether these open lesions were not secondarily infected by the organism; and second, whether the presence of the organism was not, even in the closed lesions (the adenopathy), due to the fact that it was carried to the lymphnodes by the lymphatics from adjacent open lesions.

Buschke,[29] on May 11, 1905, discovered the treponema in the organs of an infant ten weeks old who had died of heredosyphilis. The child's father was suffering from a general papular syphilide. The autopsy, made 36 hours after death, showed an indurated spleen, edema of the lungs, hemorrhagic nephritis, and hepatitis. Smears made from the liver and spleen showed spirilla having the characteristics of *Treponema pallidum*, and a specimen which was sent to Schaudinn was declared by him to contain treponemata pallida. No treponemata were found in the lymph ganglia or papillæ of the skin. He and his assistant, Fischer, hesitated to conclude, from this single observation, as to what part the *Treponema pallidum* played in the etiology of syphilis, as their examination was made upon the cadaver, and it was possible that the treponema had come post mortem from the intestines, or, since during life the infant presented open cutaneous lesions, the infection had traveled from without.

Buschke and Fischer later discovered some of the organisms of Schaudinn in smears made from the same infant's blood prior to death, but they still reserved their decision. At about the same time Levaditi[30] discovered the *Treponema pallidum* in bullæ of pemphigus which were still closed, in the liver, spleen, marrow of bones, and most of the organs of a newborn infant of syphilitic parents. Consequently Buschke, Fischer and Levaditi considered the presence of the *Treponema pallidum* in the tissues of heredosyphilitics as an argument in favor of its being the causal agent of syphilis. Numerous investigators of the subject are now convinced *that wherever the Treponema pallidum is found in the tissues there is syphilis.*

Schereschewsky,[31] in 1909, and Mühlens,[32] in 1910, succeeded in cultivating the *Treponema pallidum*, but were unable to produce syphilis in animals by means of their cultures. The Mühlen cultures were pure; those of Schereschewsky impure. Bruckner and Galasesco,[33] 1910, produced a syphilitic orchitis in a rabbit by means of impure cultures, and Sowade,[34] 1911, caused a generalized syphilis in a rabbit through an intracardial inoculation of a culture.

The three last-named investigators were unable to obtain a second generation of their cultures; hence there is a question as to whether the syphilitic lesions in their animals were due to cultivated spirochetes or to the original organisms which they intended to grow. Hoffmann[35] obtained pure cultures of the *Treponema pallidum* and has recently produced a specific orchitis in rabbits by inoculating a pure culture derived immediately from human tissues.

The *final proof* that the *Treponema pallidum* is the contagium of syphilis we owe to Noguchi,[36] 1911 and 1912, who has obtained pure cultures of *Treponema pallidum*, first, in serum water (sheep, horse, rabbit) to which a small piece of sterile rabbit tissue has been added; second, in a medium consisting of 2 per cent. alkaline agar and one part of ascitic or hydrocele fluid, at the bottom of which has been placed a piece of sterile rabbit tissue (kidney or testicle).

For the purpose of cultivating the *Treponema pallidum* he first used, "unlike all previous investigators," the *Spirochæta*-containing testicular tissue of a rabbit which had been inoculated with human syphilitic material instead of directly employing the human syphilitic material. "From this first generation in rabbits any number of generations can subsequently be obtained by transmitting the strain at

appropriate intervals from rabbit to rabbit." Noguchi employed as material for obtaining his cultures twelve different strains of pallida which were passed into rabbits through many generations, and succeeded in producing in rabbits which had been inoculated with material from pure cultures a typical syphilitic orchitis, in the lesions of which are to be found numerous *Treponemata pallida*.

Noguchi has also cultivated the organism of Schaudinn, obtained directly from human syphilitic lesions, in a solid medium consisting of a 2 per cent. alkaline agar, ascitic or hydrocele fluid, and sterile rabbit tissue. Three of the four strains worked with were successfully cultivated. The organisms grow only under strict anaërobic conditions; their morphology is typical under optimum cultural conditions; in cultures they multiply by longitudinal division; and, finally, the cultures do not produce any putrefactive odors. Most important are the facts which Dr. Noguchi has called to the writer's attention; that, the pure cultures of the *Treponema pallidum* obtained by him are grown only in a medium containing sterile tissue, and that they do not produce any putrefactive odors. The cultures of *Treponema pallidum* as obtained by Muhlens and Hoffmann, grown upon a medium devoid of fresh tissue,

Fig. 20—Dr. Halberstadter, Dr. v. Prowazek, Karl Leschner (Porter). —From Neisser's Beitrage zur Pathologie und Therapie der Syphilis.

do produce strong putrefactive odors, and in this respect cannot be differentiated from cultures of *Treponema microdentium* (Noguchi), (the *Spirochæta dentium* of Koch, or small *Spirillum dentium*), obtained by Noguchi in a medium containing sterile rabbit tissue; because these last named organisms also produce putrefactive odors.

"Inoculation of the pure cultures of the *Treponema pallidum* into the skin of two species of lower monkeys was followed by the production of lesions resembling the primary lesion occurring in man and those caused in the monkey by inoculation of spirochæta containing serum from human sources."

Noguchi has still further shown that during the course of the positive inoculation in the monkey with his pure cultures made directly from human syphilitic material the blood develops the property of giving a positive Wassermann reaction. He thus supports the relation of *Treponema pallidum* to the Wassermann reaction, and establishes the identity of the cultivated strains with the species found in human syphilitic lesions.

Fritz Schaudinn died at not quite the age of thirty-five, on June 22, 1906, fourteen months after the publication of his memoir on the discovery of the *Treponema pallidum*. His work will ever remain celebrated in the annals of the history of medicine, not only because of his discovery of the cause of syphilis, but also because it blazes the trail for the work of a host of investigators. Among the

Fig. 21—Dr. Bruck, Dr. Kaiser, Karl Leschner (Porter), Pof. Neisser From Neisser's Beitrage zur Pathologie und Therapie der Syphilis.

results of the recent investigations (all of which, except the microscopical technique, were dependent upon experiments upon animals and those men who offered themselves for experimental purposes) we have such priceless benefits to mankind as:

Fig. 22—Geh. Obermedizinalrat Prof. Dr. Paul Ehrlich and Dr. S. Hata.

1. An exact knowledge of how the syphilitic infection takes place.

2. A better knowledge of the pathology of syphilis, largely due to the work of the Java expedition composed of Neisser, Bärmann, Halberstäder, Siebert, Bruck, Kaiser, and von Prowazek.

3. A better knowledge of the treatment [illegible]se of syphilis.

4. The prophylaxis of syphilis.

5. The means of diagnosing early and positively the most infectious forms of syphilis by the various staining methods, the Burri method, and especially by the dark field microscope.

6. The application of the seroreaction of Bordet and Gengou by Wassermann, Neisser, and Bruck in the detection of syphilis; the improvement of the Wassermann reaction by Landsteiner, Muller, and Potzl; Noguchi's luetin; the cytodiagnosis of Nissl, and the globulin reaction of Nonne-Apelt.

7. The discovery and application of salvarsan by Ehrlich and Hata.

8. (Assuming that the old-fashioned practitioner and professional doubter will be proved justified in their present arbitrary denial of the value of the work of the men mentioned above) a great advance toward and aid in the probable discoveries yet to be made relative the nature and cure of syphilis and some other diseases.

PAPILLOMA OF THE VOCAL CORDS CURED BY RADIUM.

By ROBERT ABBE, M.D.,

NEW YORK

SURGEON TO ST. LUKE'S HOSPITAL

Of all the surgical conditions encountered in the human larynx, excepting cancer only, that of warty vegetations on the vocal cords, is the most rebellious to cure, obstinate in recurrence, destructive to the voice, and menacing to breathing.

It has been claimed that this condition occasionally changes to one of malignancy by irritation of the basal cells, but it is probable that this occurs as infrequently as in warts upon the skin.

One of the most persistent and unchanging cases to illustrate this point has been recorded by Dr. W. L. Culbert of this city, who published in 1904 (see the *Laryngoscope*, St. Louis, September, 1904) the history of a woman whose larynx he had repeatedly cleared of masses of obstructive papillomata by cutting punches. This case was a legacy to him from Dr. Lincoln, who had done the same, and who only continued to do what had been done by Dr. Elsberg, America's pioneer laryngologist. The picture of this larynx stuffed with warty growths was illustrated by Dr. Elsberg in a report of the case to the American Medical Association in 1865 and published in the Transactions for that year.

The patient had had her larnyx cleared out every six months for over forty-seven years. When Dr. Culbert presented her case to me for radium treatment in February, 1908, the growths were still non-malignant, but obstructive. A large part of

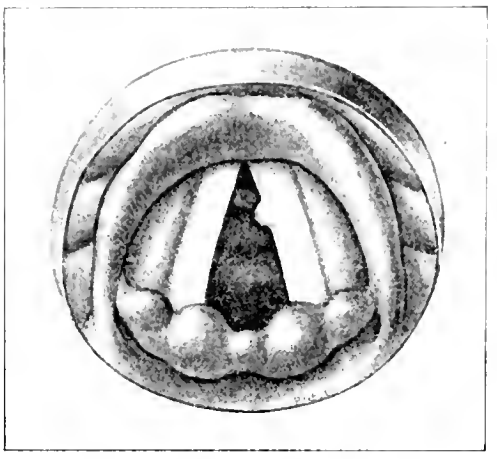

Fig. 1.—First fibroma removed by punch.

them were rapidly dissipated by radium applications. Dr. Culbert reports that he did not operate during the three years subsequently and the larynx was clearer than he had ever seen it without operation. "She also now breathes freely enough with one-third of the larynx entirely free from vegetations."

Believing that warts within the larynx ought to be as perfectly curable by radium as warts on the skin, lips, tongue, or eyelids—for which it is a specific—I now treated with great interest and perfect success a striking illustration of the same condition of laryngeal papillomata in a young woman referred to me also by Dr. Culbert.

The illustrations shown herewith in series, demonstrate the appearance, type, and course of the disease from its incipiency to its worst condition when the patient came under my care, and, finally, a picture of her restored vocal cords six months after my treatment by radium.

This attractive young woman of seventeen years had an unusually sweet singing voice which became

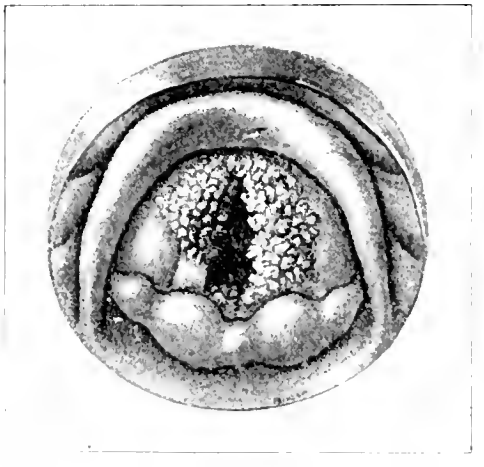

Fig. 3.—Condition when treated by radium.

hoarse in July, 1910. She applied to Dr. Culbert in September, 1910, who found the growth on the left vocal cord, as shown in Fig. 1. He excised it and submited it to Dr. Ewing, who regarded it as a "fibroma." A rapid recurrence took place looking larger and like papilloma in its rougher surface (Fig. 2). Again it was excised with thoroughness, but not examined.

Again a rapid recurrence looking more dusky and more like sarcoma than papilloma. It occupied the

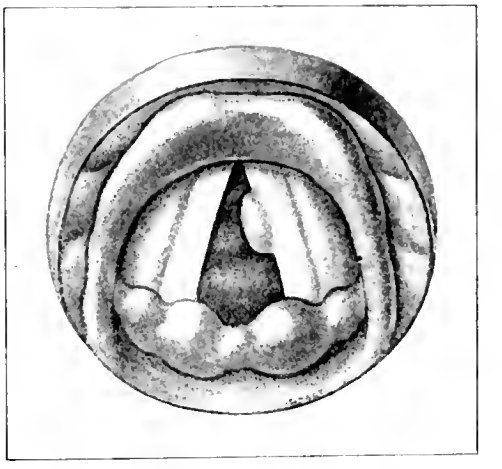

Fig. 2.—Return tumor removed by operation.

central half vocal cord and overflowed somewhat into the ventricle.

Attempts to apply radium when she was submitted to me at this stage were not satisfactory owing to the patient's restlessness under difficult laryngeal anesthesia in spite of Dr. Culbert's patience and skill.

The growth progressed rapidly now as a papilloma. By June, 1911, the voice was entirely gone and respiration was obstructed. The accompanying picture shows the growth at that date (Fig. 3).

On June 14 I did a tracheotomy under ether anesthesia, and through this wound passed a wire up through the larynx into the mouth. By this means I drew up into the larynx a small smooth capsule containing 100 milligrams of pure radium, which was thus suspended precisely between the vocal cords. Here it was held for thirty minutes while anesthesia was continued through the tracheotomy opening. No further care than this one treatment was given.

During the summer the patient gained steadily

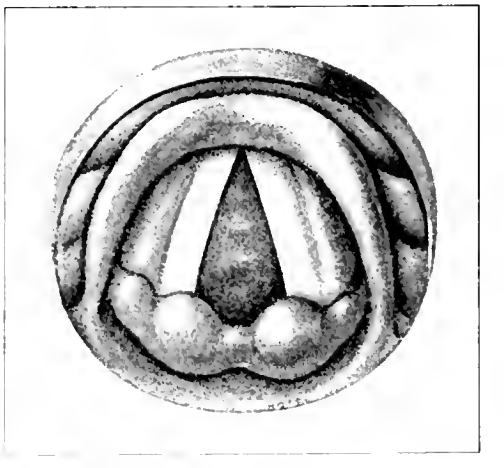

Fig. 4.—Restoration to normal, six months after one radium treatment.

and three months later, when examined by Dr. Culbert and myself, no trace of the growth remained.

Six months later the patient was shown at the Practitioners' Society and demonstrated her perfect restoration of singing voice. The illustration

was now made (Fig. 4) of her perfectly healthy vocal cords as seen by the artist and others. No disease or scar can be detected.

Two other cases of intractable papillomas of the larynx, one even extending into the trachea, have been treated by me with demonstration of the same reducing action of radium. Both are still under treatment and promise ultimate cure of the extensive growths.

PEDIATRIC MEMORANDA.

CONGENITAL MYXEDEMA — CYSTIC GOITER WITH FEEBLE MENTALITY.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

Cretinism in children is due to partial or total arrest of the secretion of the thyroid and parathyroid glands, in consequence either of congenital or acquired (extirpation) absence, atrophy, or goitrous degeneration of the gland. In the first case under our observation the myxidiocy developed apparently as a result of congenital absence of the thyroid, in the second case the feeble mentality was due to goitrous degeneration.

Congenital Myxedema.—The little girl was six months old when her photograph was obtained. She seemed quite normal at birth, and for the first few weeks subsequently while breast fed (has probably received an ample supply of thyroid through the mother's breast milk). A few weeks later, however, the child's appearance began to change. The baby was growing unusually plump, though partaking but little nourishment and occasionally suffering from indigestion. She showed a marked tendency to persistently protrude the tongue, to snore heavily while asleep, and to "grunt" while awake. The mother and her good neighbors could readily

Fig. 1.—Congenital myxedema.

explain away the plumpness and the protrusion of the tongue, attributing the former to her unusual good temper (for she was for ever sleeping) and the latter either to teething or to a "craving for something to eat the mother must have longed for during pregnancy—and could not obtain"; but the noisy breathing they rightly thought was not natural for a healthy child, hence they decided to see a physician. The baby was examined by several physicians, privately and in dispensaries, and it finally came under my observation. As can readily

Fig. 2.—Cystic goiter with feeble mentality.

be seen from the accompanying illustration (Fig. 1), the case was characteristic. The head was broad, flat, and plump and set upon a thick and short neck. The forehead was low and the root of the nose broad. The anterior fontanelle was widely open and the cranial sutures were barely united. The hair, though long, was lustreless, sparse and brittle. The face was waxy, apathetic, lifeless, marbleized, as it were, and much older in appearance for the child's age. The eyelids were puffed, and the eyes spindle-shaped, dull and dreary, but not profoundly idiotic—she recognized the mother and was annoyed by the approach of strangers. The tongue was extraordinarily large, pale, and thick, entirely too large in size comfortably to be accommodated in the oral cavity, hence ever protruding and snugly embraced by the deathly pale, unusually heavy lips. The anterior portion of the neck was thin and loosely covered by wrinkled skin and subcutaneous tissue. Careful palpation failed to locate the thyroid gland even in rudimentary form, the space normally allotted to it being apparently free from any soft structures suggestive of thyroid tissues. The supraclavicular and subclavicular spaces were filled in by so-called "fatty-tumors." The abdomen was pendulous and flabby and marked by a large umbilical hernia. The articulations of the extremities were thickened, and the hands greatly resembled the so-called "trident-hand," *i.e.*, peculiar fan-like divergence of its thick, almost uniformly sized fingers. Under moderately large doses of thyroid gland substance the child usually brightened up considerably, but the idiocy invariably returned on discontinuance of the medication.

With so typical a clinical picture the diagnosis of congenital myxedema or cretinism could readily be

made, almost at a glance. In less pronounced cases, however, errors of diagnosis are quite possible. For example, macroglossia with rachitis or Mongolian idiocy in infants *under six months* have several symptoms in common with myxidiocy, and may for a time keep the physician guessing. But in macroglossia we usually find that the tongue seemed largest at birth and became gradually *relatively* smaller as the baby grew older and its oral cavity larger; furthermore, the child's mentality is not affected. Mongolian idiocy, while, like congenital cretinism, characterized by idiocy and protrusion of the tongue, presents entirely different facial and cranial features. Thus, the cranium of the Mongolian idiot is somewhat smaller than normal, rounded, with the occiput running quite parallel with the plane of the face. The face is sunken, the cheek bones are prominent, the nose is short and broad and bound laterally toward the eyes by distinct vertical folds. Finally, all forms of athyreosis improve under the administration of thyroid or parathyroid gland substance, while this is entirely useless in congenital macroglossia or Mongolian idiocy. Hence the advisability of resorting to this therapeutic test in all cases of doubt.

Cystic Goiter with Feeble Mentality.—In this case I was unable to conclude whether I was dealing with a case of hypothyroidism or hyperthyroidism, since, while her bodily development precluded a deficiency of thyroid, her gradually developing feeble mentality simultaneously with the progressive goitrous degeneration of the thyroid gland fully justified such an assumption. When I first saw her she was thirteen years old. She was five feet six inches in height, and slender in build, weighing one hundred and twelve pounds. Her general health was good and her heart's action slow and regular. Her menstruation had not set in and her mammary glands were not developed. Her head was large and covered by a fair supply of normal hair. Her eyes were large, but not bulging, and her facial features seemed normal, when she was not laughing—which latter was rarely the case, especially when spoken to. When addressed she would invariably grin (that peculiar idiotic grin) or laugh aloud for several minutes at a time, open her mouth very wide and show a set of ugly, big, blackish brown, partially decayed, crooked teeth. Examination of the neck revealed (see Fig. 2) a large, elastic, cyst-like swelling, spreading out as a broad goitrous mass, especially to the right. According to the mother the tumor developed gradually within about two years previous to my examination. The family history was apparently negative. The parents were hard-working, healthy people, and their two other children were well. The patient's mental condition was supposed to have been quite good up to ten years of age. At about that time it was noticed that she lost interest in her school work, became slovenly and forgetful and very "nervous." As weeks and months passed by her feeble mindedness grew more and more pronounced, so that on coming under my observation I found her essentially idiotic. As already stated, when addressed she would grin and laugh; when questioned about something, she would turn to her mother and partly repeat what the mother had to say; she was unable to add together, for example, two and two, and had not any idea of where she lived. She was extremely restless and disturbed by the slightest commotion, and like a frightened baby was closely clinging to her mother's side. I put her on slowly increased doses of thyroid extract, but it seemed to have no beneficial effect upon her feeble mentality—her condition remained stationary for several months. I lost track of her for about six months thereafter, when one day I read in the daily press that on being sent to a grocery store across the street she had lost her way back home and was picked up by a policeman the following day, exhausted from hunger, thirst, and fatigue, wading knee-deep in the swamps of Westchester and unable to give any information as to her name or place of residence.

127 West Eighty-seventh Street.

EXAMINATION OF THE DUODENAL CONTENTS FOR DIAGNOSTIC PURPOSES TO CLEAR UP CERTAIN AFFECTIONS OF THE UPPER ABDOMINAL REGION.

By M. GROSS, M.D.,

NEW YORK.

As it is not always possible to correctly interpret pains located in the upper abdominal region or to establish the cause of such pains, any method that may be instrumental in elucidating these conditions should be availed of. There are notably the macroscopic, microscopic, and chemical examinations of the duodenal contents by means of the duodenal tube devised by me,[1] which methods seem capable of pointing the way to an elucidation of these frequently veiled conditions (affections of the stomach, pancreas, duodenum, gall-bladder, and liver). It may be opportune to commence with the description of a concrete case in order to better illustrate the points at issue and also to show the extent to which microscopic examinations of the duodenal contents can in certain cases be made serviceable for diagnostic purposes.

Mrs. S. T., 28 years old, mother of three children, was first examined by me on July 20, 1911. Family history negative. According to her statement, has always been in perfect health until five years ago, when she contracted a cough which, however, completely disappeared after a few months. Soon afterwards, and shortly after a delivery, she commenced to suffer from sporadic paroxysms of "stomach cramp," which often lasted for hours, often came during the night, radiated toward the right shoulder, were accompanied by nausea and followed by debility; in short, the characteristic picture of gallstone colic. During the last few months the paroxysms were more frequent and severe. She never vomited and stated she never had had a yellow complexion. Menstruation always regular.

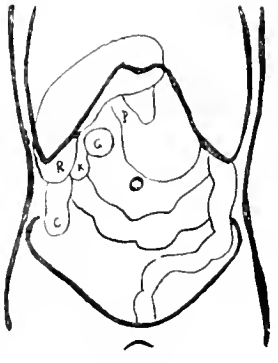

Fig. 1.—P, pyloric part; G, gall-bladder; K, kidney; R, Riedel's lobe; C, cecum.

General examination showed a pale, emaciated

woman of slight structure. Mucous membranes pale, the scleræ slightly yellowish discolored. Reflexes rather exaggerated. Temperature normal. Cardiac findings negative; vessels hypoplastic. The right apex of the lungs reveals distinct traces of an old affection that has run its course. Urinary findings negative. Abdominal inspection shows at the first glance two distinct protuberances (see photographic illustration). The bulging at the left side of the median line corresponds to a displaced, dilated stomach which is just undergoing a stiffening, advancing to the pars pylorica, and rendering the same visible. The protuberance in the right hypochondrium corresponds to an enlarged gall bladder. On inspiration the latter can be distinctly seen to move downward, returning to its original position on expiration. By means of abdominal palpation nearly all the organs are found to be prolapsed and can be distinctly palpated through the attenuated abdominal walls (Fig. 1). The enlarged gall bladder has the size of a small hen's egg, is pear-shaped, smooth, firmly elastic, but not painful, freely movable in all directions, with the fixation point in the region of the cysticus. Patient states that she could see and feel the enlargement for the past three years. The liver is smooth, of normal consistency, and slightly extended beyond the costal margin in the mamillary line. The left lobe appears normal, whilst toward the anterior right axillary line a sharp, tongue-shaped process can be distinctly felt, similar to a floating kidney, but thinner, more superficial, and continuously passing into the hepatic tissue. This is the so-called "Riedel's lobe" (or "Schnurlappen").* The liver itself is not susceptible to pressure with the exception of one point close to the left margin of Riedel's lobe in the region of ampulla of the gall bladder and the ductus cysticus.† The gall bladder itself is not very susceptible to pressure from without (Lenander); when patient is at all conscious of any pain during these manipulations, she refers it to the region of the neck of the bladder where it joins the ductus cysticus, which means lower down, below the liver. Also during the paroxysms patient had frequently occasion to observe that the pain manifested itself at the place just described, and this might perhaps be regarded as pointing to the cause of the pain in "colicky attacks." The causation of the pain can certainly not be attributed to the pressure of an inflammatory exudate alone (Aschoff and Bacmeister), because in that case any exaggerated pressure upon the gall bladder, such as I have often exerted, would produce a paroxysm which, however, has happened only once and then only momentarily. Nor can a "muscular spasm" be held responsible for the pain, since the above named authors have found that at the spot where the calculus is most frequently impacted, the cysticus possesses practically no muscle fibres at all. On the other hand, a typical colic may occur without concrements, as for instance in cholecystitis, in cholangitis (Riedel) and in adhesions. Inflammatory manifestations of the mucosa itself can only be considered as causes of these colics, if erosions or ulcers should simultaneously develop at the same place, where in that case the lightest touch or contact is capable of causing the most exquisite paroxysms, notably owing to the abundance of sensitive fibres at these very parts. Inquiry among surgeons has partly confirmed this view.

Distinct splashing sounds, extending below the umbilical region, can be elicited in the gastric region, six hours after ingestion of a light meal (stagnation). On digital examination the contracting pars pylorica can be palpated as a cord the thickness of a finger, running toward the liver upward and to the right.

On July 21 the gall bladder was tapped and a very small quantity of a clear viscid fluid was evacuated and found sterile. On July 22 the stomach was examined before breakfast and 40 c.c. of contents withdrawn which contained distinct food remnants of the previous day. Congo positive. This was followed by lavage of the stomach and immediately afterwards by insertion of the duodenal tube. After half an hour clear, golden yellow duodenal contents were withdrawn which contains the three ferments: trypsin, steapsin and amylopsin, in distinct quantities.* No blood was found, either macroscopically or chemically. The first duodenal lavage† was made with warm distilled water. On July 24 patient reported a violent gallstone colic on the previous day, stating that the tumor felt larger and harder during the paroxysm (contractions of the hypertrophic wall of the gall bladder). Local examination resulted in the same findings of the gall bladder as at the first examination. The stagnant gastric contents showed free HCl 40, total acidity 60. Lavage of both stomach and duodenum was done at once, as on all succeeding days of treatment. The duodenal tube was introduced to about "80," which means 80 cm from the teeth, or a few centimeters beyond the caruncle, but still this side af the duodenojejunal juncture. This time the duodenal lavage was made with a decinormal HCl solution, we being led by the idea (1) to cause reflex closure of the pyloric ring and (2) to prevent regurgitation of the duodenal contents into the stomach, and thus to have a still better chance of causing a reflex action of the gall bladder. July 25. There was no paroxysm of pain, but a passing diarrhea following the duodenal lavage (intestinal irritation). This day, for the first time, a few calculous concrements were found in the aspirated duodenal contents. Gastroduodenal lavage instituted. July 26. Patient had no pain and the local findings were unchanged. Temperature 99½°. No lavage was done this day. July 27. Last night patient had a violent paroxysm. There was distinct stagnation of the gastric contents. Gastric lavage. Microscopic examination of the aspirated duodenal contents revealed in spite of the thorough lavage of the stomach small quantities of starch granules, which are a sign of duodenal stagnation,† little neutral fat in minute droplets, fatty acids, little mucus, no epithelia and no concrements. By way of experiment the duodenal lavage was this time made with a Carlsbad salt solution (4 to 250). Upon withdrawal of the duodenal tube a large quantity of regurgitated duodenal contents was found in the stomach.† On July 31 patient reported a number of painless days and felt more hopeful. The gall bladder was unchanged in shape, size, etc. Stagnation of gastric contents was con-

*The origination of this lobe is not yet quite cleared up, but it is a fact that in the presence of Riedel's lobe gallstones are found in the reservoir system (L. Arnsperger).

†Probably in consequence of inflammatory processes and adhesions, which are particularly prone to establish themselves at this point, and also in consequence of the large number of sensitive fibers there (Aschoff and Bacmeister).

*The ferments were examined in accordance with our simplified method, as described in the MEDICAL RECORD, November 12, 1910.

†The infused alkaline solution prevents the reflex closure of the pylorus; hence the unusually large quantity of massy regurgitation.

siderably less. Gastrointestinal lavage was done as usual. In order to prevent regurgitation due to duodenal lavage, two measures were adopted: (1) The duodenal tube was inserted deeper (85 cm) and (2) patient remained in the right recumbent position during the entire procedure. As a consequence, regurgitation during the duodenal lavage was considerably less. Microscopic: In the pure duodenal secretion few but distinct concrements. On August 3 patient again reported a painless day. On palpation the gall bladder for the first time gave the impression of being smaller and less resistant (owing to a more abundant evacuation of the gall bladder). On August 4 the report was again favorable. The aspirated duodenal contents appear somewhat darker and more viscous. (Bladder contents.) Microscopic: Large quantity of cholesterin crystals of different sizes, sometimes covering the entire field of vision. Besides, the preparation shows a large quantity of concrements in greater accumulation, dark red to brown with a dull lustre and arranged in piles; furthermore small scales, dark red to brown of strong refraction (bilirubin crystals).* On this occasion I was also able to observe, for the first time in this patient, a distinct strangling effort at the moment the small ball of the

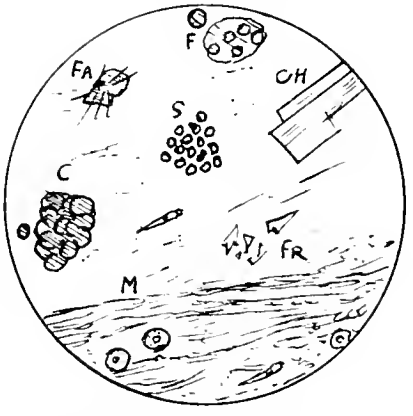

Fig. 2.—M, mucus with embedded cells and epithelia; C, concrements; S, starch granules; Fr, fragments; Ch, cholesterin crystals; Fa, fatty acids and crystals; F, fat.

duodenal tube passed the pyloric ring while withdrawing the tube (60 cm).

There was a fresh paroxysm in the night from August 5 to 6. On August 6 the gastric stagnation was again more pronounced. The enlarged gall-bladder again felt replenished. (Calculous impaction and renewed stagnation of the bladder contents.) Gastroduodenal lavage. August 8. Patient complains of a more constant pain in the hepatic region in the intervening days and of anorexia. Temperature 99°. Bladder is smaller, and of a rounder contour than pear-shaped, and not painful. (Renewed partial exacuation of the cystic contents, the bladder containing almost nothing but gall stones.) On this day the duodenal lavage was experimentally made with filtered lemon juice (4:200). We then also succeeded for the first time, although only under simultaneous pressure on the gall bladder from without, in evacuating large quantities of bladder contents *i.e.*, the fluid obtained in the "receptacle" was much more turbid and dark, more nearly black-brown and, which is important, of a viscous consistency, transfused, as it were, by mucous clouds, which would indicate distinctly characteristic gall bladder contents. Microscopic: Numerous cholesterin tablets, brown concrements arranged in piles, but also in minute fragments and particles as well as free minute globular deposits of brick-red to brownish color. A few formed elements were embedded in the mucus; the cells were somewhat larger than leucocytes (Fig. 2) (Petry). As to spindle and polygonal cells, observed by the same author, I have not yet been able to discover any. The duodenal contents thus obtained, with a distinct admixture of gall bladder secretion, was now examined for typhoid bacilli, with a negative result.*

At this juncture I may be permitted to interpolate the following statement: The microscopic inspection of the duodenal contents, as it is gathered with the aid of aspiration in the "receptacle" of the instrument, enables one after a short experience to draw certain conclusions as to the part of the duodenum from which the fluid emanates. Thus, in the pars superior duodeni the contents are more likely to resemble gastric contents, although there are already all the characteristics of the duodenal contents, such as reaction, color, and oftentimes ferments (secondary stomach, "Nachmagen"). A few centimeters lower down, but still above the caruncle (papilla of Vater) they have all the properties of pure duodenal contents, that is, they are alkaline, limpid, viscid, fluid, light yellow to green or golden yellow; in rare cases it is even possible to obtain pure duodenal secretion, or rather intestinal secretion, *i.e.*, without an admixture of bile. This fluid has a lighter color, scarcely yellow. In the pars inferior, a few centimeters lower still and below the caruncle, the duodenal contents may show the same characteristics as above the caruncle, but (when the stomach is empty, in irregular and infrequent intervals), the duodenal contents will contain also a wave of the characteristic bladder contents. In normal conditions, *i.e.*, under the stimulation of ingested food and the reflex impulse of the latter, the inspissated bladder bile, mixed with the now abundantly secreted liver bile, flows freely into the duodenum at the beginning of digestion and at the opening of the so-called duodeno-choledochal sphincter. When, however, this sphincter is closed, there is an obstacle to the flow of bile, compelling it to take its course through the cysticus and gall bladder (Pawlow). In our present case, as long as nothing but pure duodenal contents could be aspirated, this occurrence points to an occlusion of the cysticus, and only the increased flow of characteristic gall bladder contents showed that the cysticus became, even if only temporarily, unoccluded.

On August 10 patient did not complain of pains, but had experienced a severe paroxysm between August 10 and 11. It is a remarkable fact that almost regularly after each colicky attack there is a stagnation of the gastric contents, probably due to the reflex spasm of the pyloric muscle occurring in cholelithiasis, as observed by Büttner. On August 13 patient produced a calculus which had been voided with the stool. It was nearly the size of a cherry stone, of light yellow color, hard, and rough on the surface. Cross-section showed an irregular stellar nucleus with no layers (cholesterin-bilirubin-

*Minute, almost colorless, particles of great refractive power, which are often found microscopically, arranged in heaps, are minute starch granules, which should not be confounded with "free concrements."

*Weber was the first to examine, after Volhard's method, the duodenal contents for typhoid bacilli (*Münchener medizinische Wochenschrift*, 1908, p. 2443). It is, of course, necessary to interpret these findings with caution, since the pancreatic secretion was found to be extremely bactericidal.

calculus). A finely powdered portion of the calculus showed under the microscope that it was of exactly the same character as the concrements mixed with the duodenal contents; so were the particles obtained by beating the stone with a glass rod (Petry). From August 13 to September 2 the pathological picture repeated itself in the manner before described: Paroxysms of pain and replenished gall bladder alternating with painless days, sometimes but not always accompanied by reduced swelling of the gall bladder. The method of treatment also continued in the same way as before. On September 2 every attempt at reducing the gall bladder, even under exaggerated pressure, was futile. (Complete irremovable occlusion of the cysticus.) Treatment was now interrupted and operation advised, which patient however flatly declined.

The diagnosis in the present case was not open to doubt from the very first. There was a dropsical gall bladder with hypertrophic walls, containing biliary calculi. Probably there was also a chronic ulcerative process at the neck of the gall bladder. The entire process may have developed in two phases. In the first phase there was a non-inflammatory stage with simple biliary stasis without the co-operation of bacilli, with formation of so-called pure "radial isolated cholesterin calculi" (Aschoff and Bacmeister, "Die Cholelithiasis," Jena, 1909).* In the second, or inflammatory, phase there is, according to the authors named, a "radically different" ("prinzipiell verschieden") biliary calculous formation: the "secondary mixed calculi" (cholesterin-pigment stones); contrary to the old theory of Naunin that every gall stone formation required the presence of both stagnation of bile and bacterial infection.

E. Petry, of Gratz, was the first to show[4] that gall bladders containing calculi also contain smaller concrements of the same nature as the calculi, whether as "free" deposits or as fragments of the larger stones. If then, he argues, it should be possible to demonstrate these concrements in the bile, the proof of the presence of biliary calculi in the gall bladder would be adduced. His method is as follows: In accordance with Volhard's[5] suggestions he introduced 200 grams of oil into the empty stomach and after about an hour examined the contents regurgitated from the duodenum for these concrements. It is owing to the method adopted that Petry was unable to obtain pure duodenal contents, *i.e.* unmixed with gastric juice, even when administering the oil upon an empty stomach, being that even in the normal empty stomach there are often small quantities of contents, and always mucus, epithelia, etc. It is due to this fact that the results obtained may lead to errors. On the other hand, with the duodenal tube devised by me it is possible to obtain pure duodenal contents in a relatively short time, sometimes already in half an hour. The demand for a rational internal treatment of biliary calculi would according to P. Meyer[6] be fulfilled if, in the first place, biliary stasis were prevented, which he proposes to do by "fluidification of the bile." This should be accomplished by copious drinking of hot water in the morning and evening, and by partaking of frequent small meals, since the duodenocholedochal sphincter is patent during digestion, dependent upon the entrance of food from the stomach into the intestine, and thus would be instrumental in frequently renewing the bile supply. In the second place, it would be necessary in the internal treatment of gall stones, to stimulate intestinal peristalsis in order to incite the "muscular power of expulsion of the gall bladder contents," thus promoting the secretion of bile. Lavage of the stomach with hot water is also intended to serve the same purpose (Ewald). All this was the leading idea in applying and pursuing my purely mechanicotherapeutic proceeding in the present case; it would be hard to devise a more purposeful and direct proceeding. But as I have already intimated in my article on the "Lavage of the Duodenum"[7] duodenal irrigation is probably ineffectual in gall-bladder affections for therapeutic purposes. As was to be expected, the success could only be nominal, although the desired reflex effect of lavation upon the gall bladder could be directly demonstrated (palpable contractions of the gall bladder; evacuation of the small calculus). It is conceivable that the small stone would have passed without any mechanical assistance, but a passage of larger stones could most certainly not be effected by this method.

In conclusion I may be permitted to emphasize a few more diagnostic points. The distinct stiffening

Fig. 3.—Showing the stomach in peristalsis and the enlarged gall-bladder.

of the stomach in the present case was assuredly not caused by a hypertrophic pyloric stenosis, as has usually been assumed up to the present, because the duodenal tube passed smoothly through, which is not always the case in constrictions at the pylorus. The causes for the stiffening of the gastric wall might have been (1) an angulation of the pars superior duodeni,[8] (2) pressure of the enlarged gall-bladder upon the duodenum; or, perhaps, (3) adhesions emanating from the ampullar part of the gall-bladder and connecting the same with the pyloric part of the stomach or duodenum—adhesions which are capable of exerting a disturbing effect upon normal function of these parts. The pyloric spasm certainly could also have assisted in a stenosis of the pylorus, even though temporarily. It must be left to further investigations to find out whether and how far a duodenum hanging down in a weak condition, in which apparently the food is more or less stagnant, as in the present case, can exert an influence upon the motility of the stomach; and it will also have to be shown in how far duodenal affections can give rise to painful paroxysms in the upper abdominal region (Lane). Furthermore, the fact was

*Reidel, too, believes in the non-bacterial mechanical development of hydrops vesicæ fellæ.

of diagnostic importance that in all duodenal examinations in the present case "macroscopically visible blood specks" were not mixed with the duodenal contents on a single occasion, as their presence would have been a sure sign of duodenal ulcer, as I have pointed out[9] on a previous occasion.

CHEYNE-STOKES RESPIRATION WITH REPORT OF TWO REMARKABLE CASES.

By DAVID FELBERBAUM, M.D.,
NEW YORK,
PATHOLOGIST TO THE MONTEFIORE HOME
AND
SAMUEL EHRENREICH, M.D.,
NEW YORK,
HOUSE PHYSICIAN OF THE MONTEFIORE HOME.

This type of respiration, occurring as it does in the course of various conditions, has aroused a great amount of interest and produced a corresponding number of contributions to medical science. Hippocrates, in the First Book of the Epidemics, makes reference to it; Nicolas, in 1780, gave a full description of the ascending phase of Cheyne-Stokes respiration, but did not mention the period of descending respiration. With the above exceptions this peculiar form of breathing remained unnoticed until Cheyne observed it anew.

Fig. [illegible] (Case II) at level of exit of fifth cranial nerve, showing the numerous scattered foci of degeneration.

In reporting a case in 1818, of fatty degeneration of the heart, Stokes, whose name as well as Cheyne's is now indissolubly bound up with the peculiarity of breathing, made it pathognomonic of fatty degeneration of the heart, saying that he had never seen it except in examples of that disease. In 1858 similar phenomena were produced experimentally by Schiff. He observed the characteristic breathing as the result of hemorrhages involving the medulla oblongata but not directly affecting the vital spot. Von Basch, Little, Benson, Traube, Mader, Gibson, and many others have written very valuable treatises upon this subject; it is Gibson, especially, who has gone into it in detail.

Among the conditions in which the Cheyne-Stokes respiration is seen are various cardiovascular affections, such as fatty heart, coronary sclerosis, noncompensated aortic stenosis, arteriosclerosis; various severe affections of the brain, such as tumors and hemorrhage; various diseases of the respiratory apparatus, and chronic nephritis. The administration of morphine has occasionally produced it. Although more frequently observed in the unconscious it is not uncommon even when consciousness is maintained, especially in patients with chronic respiratory or circulatory disorders.

The explanation of the cause of Cheyne-Stokes respiration is still not wholly agreed upon. It is an indisputable fact that it depends upon a reduction of irritability of the respiratory center. The original theory of Traube assumed that the symptom arises when the excitability of the respiratory center is so greatly lessened by the insufficient supply of oxidized blood to the medulla that, at a certain moment coinciding with the first breathing pause, there is no longer a sufficient physiological stimulus to arouse the respiratory movements. With the cessation of respiration the blood becomes still more decidedly venous. This irritates the respiratory center intensely, so that despite the diminished susceptibility, breathing begins again. This in turn diminishes the venous character of the blood, and the breathing gradually becomes weaker in proportion to the oxidation of the blood. Sahli explains certain discrepancies in this theory by calling attention to the fact that the blood becomes more venous even after the beginning of respiration, which accounts for the gradual increase in strength of the respiratory movements; another objection to Traube's theory is that after the respiratory center's normal excitability has been restored by an improved supply of oxygen, why should the breathing fade away again? If we hold with Traube that the asphyxia of the respiratory center is the sole cause of its diminished excitability, the objection cannot be answered; but if we regard the excitability of the center inherent and not altogether dependent on the circulation, the objection loses its force. (Sahli.)

Rosenbach maintains that the periodicity of this type of breathing results simply from an abnormal fatigue of the respiratory center, but that this fatigue should not be confused with a diminished irritability. The center is active for a time, works against a gradually increasing difficulty, finally stops entirely and begins its activity again only after the pause has to some extent recuperated its powers. Fihlene thinks that the excitation of the vasomotor center causes an anemia of the respiratory center, and thus this type of breathing. These are the three theories most generally known.

In typical Cheyne-Stokes breathing the normal rhythm is interrupted by distinct arrests of respiration; there is an alternation of periods of respiratory activity and periods of respiratory repose. The arrests of respiration in typical Cheyne-Stokes breathing occur at definite intervals of time; they are therefore periodic; another essential feature is that the period of activity consists of two distinct phases, termed by Cheyne as ascending and descending. During the former there is a gradual increase not only in amplitude of the respiratory movements, but also in their rate; while during the

latter phase there is a gradual decrease, both in extent and rate, of these movements. No hard and fast line can be drawn between the regular periodicity of events seen in classical Cheyne-Stokes breathing, and the altogether stoppages of respiration characteristic of cerebral breathing. Many other modified forms of these breathings occur, in which the irregularity varies a good deal and where periods of apnea may be absent.

During the period of repose there is an entire absence of all movement and during the period of activity the patient often appears as if laboring under severe dyspnea. Sometimes the rate of the pulse is diminished and the blood pressure falls during the apneic phase and a rise of blood pressure with quickening of the pulse occurs during the period of respiratory activity. These are the cases which, according to Eyster, are always associated with increased intracranial tension. The cases with Cheyne-Stokes respiration occurring in cardiac and arterial disease have a slowing of pulse and fall in blood pressure during the dyspneic period, and a rise of blood pressure and quickening of the pulse rate during the apneic period.

Certain eye changes have also been observed frequently, the eye being open during the period of breathing and closed during cessation of respiration. A conjugate deviation of the eyeballs has occasionally been noticed during the pause; in the latter stage the pupils are contracted and do not react, while during the active stage they widen and react once more. No changes have been observed in the condition of the vessels of the retina during the various phases of respiration.

The occurrence of Cheyne-Stokes breathing is a very grave symptom, usually being the harbinger of death, although a few cases have recovered from it. Therapeutically Eyster has attempted to treat the condition by increasing the irritability of the respiratory center; (1) by injections of strychnine, and (2) by inhalations of CO_2, and he has been fairly successful.

The two cases that we now wish to present are unique in that (1) the typical manifestations of Cheyne-Stokes respiration continued for a long period of time, and (2) they were associated with definite symptoms of pontomedullary disease and chronic nephritis, so that clinically the origin of this symptom was evidently very obscure. In the second case the periods of dyspnea and apnea each lasted for 35 seconds, which is an exceptionally long time.

Case I.—Patient, M. W., age 64, male; admitted to the Montefiore Home April 3, 1908, died May 5, 1908. Father died of cardiac disease; mother died of "softening of the brain" at 74; one brother died of stomach disease at 45, and a sister is suffering with gastric trouble. Mother had a few miscarriages, patient not knowing the number or time of occurrence. No consanguinity. About twenty years ago complained of "liver disease," was ill for a few months, jaundiced, etc. Otherwise patient has always been well previous to onset of present trouble. Habits were regular, no excesses. Venereal history unknown. Cigarmaker by occupation, worked under poor surroundings. No drug habits.

Present Illness. Three years ago was suddenly stricken with dysarthria; was put to bed where he remained for two days, after which time he could be understood. This disability of speech has continued through illness. About one year later, while sitting in a chair at home, he suddenly commenced to rub the eyes; after being asked what the trouble was he asserted that he could not see distinctly. Previous to this he felt dizzy for a few minutes. There was no history of headache or vomiting between first and second attacks. There was, however, a history of occasional dizziness. He did not work as well as usually, and attributed this to weakness. Since the second attack has been troubled with eyes, especially the right (wife says), besides a general feeling of weakness. While drinking he showed evidences of dysphagia ever since the first attack; since last attack the following mental symptoms have presented themselves: Occasional spasmodic crying and laughing spells; he became very irritable, would demand impossible attentions; memory deteriorated rapidly, and his statements were very unreliable; he became careless in his dress and habits; he often wet the bed unconsciously, but never soiled it; slept very much and lost interest in current events. About five weeks ago daughter suddenly noticed crossed eyes, patient not complaining of anything at the time; he felt somewhat dizzy and walked with the aid of chairs to the supper table; had supper, had to be carried from the table and complained of dizziness, diminished vision, and inability to walk; could move legs and arms. For the next five days could not recognize his relatives; for the following few days only recognized them by their voices. At no time had the patient a paralysis of either arm or leg. However, the left side appeared higher and drawn.

Since the last attack has had the following mental symptoms: Disoriented as to time and place; could not remember any occurrence during the day, would fabricate considerably, telling of many experiences when questioned; had greater crying spells, but less marked laughter; from time to time soiled his bed as well as wet it; dysphagia no worse. Shortly before the last attack it was noticed that patient would have peculiar respiration, which would stop at intervals, then return. A few months previous to the last attack he was taken suddenly ill with marked dyspnea and a cold perspiration lasting a few minutes. When seen yesterday patient was irritable, refused to go to bed for examination; was nonoriented; said he had kidney trouble for three weeks.

The patient is of average height, well built, general nutrition good; when left alone he lies upon his back, and only from time to time exerts himself by sitting up and asking for a glass of water; panniculus adiposus moderate in amount. The most characteristic and noteworthy condition present is the constant presence of typical Cheyne-Stokes breathing (see Tracing 1). The periods of apnea and dyspnea each lasting 20 seconds; the number of respirations during the dyspneic period is 12. Nothing characteristic in the station. The gait is that of a senile character; no ataxia or staggering.

Head is well formed; temporals very tortuous and prominent; right side of face droops, right eye shows a convergent squint; eyes are nearly in constant nystagmus, made more so by any attempt at focusing. Face is flushed and mucous membranes cyanotic; occasional oscillations of head from side to side present. First cranial nerve apparently normal; 2nd, sight is fair, but at times, especially when looking to the right, he apparently has diplopia, for he counts two fingers as four; 3rd, 4th,

and 6th, ocular movements of the left eye normal except for constant nystagmus; of the right eye there is a well-marked paresis of the external and superior recti. Arcus seniles marked; 5th, motor and sensory normal; 7th, facial innervation much stronger on the left side, pharyngeal innervation stronger on the right; 8th, hears the watch at a normal distance on both sides; 9th, apparently taste is preserved; 10th, see tracing of Cheyne-Stokes pulse, high-tension, systolic pressure, being 205 mm. Hg., diastolic 140; rate is 90 per minute, regular; vessel wall intensely sclerotic; 11th and 12th, normal. Patient is apathetic, when left alone is somnolent; asks for water spontaneously, which he drinks in large quantities; when asked a question his response is snappy and monosyllabic; absolutely resists examination. Disoriented, he is irritable, very suspicious, and is easily excited. The speech is thick, dysarthric; while questioned he would repeatedly ask, "Aren't you through yet?" Impulsive crying and laughing present. He fabricates, e.g. gives a story of having fallen from a ladder recently. Writing is very indistinct.

Active movements are good in upper as well as in lower extremities; can assume sitting posture with ease while in bed. Gross motor power fair and equal on both sides. Pupils do not react; left is slightly smaller in size than is the right, and both are irregular in outline; jaw jerk is present, supraorbital reflex exaggerated, especially on right side; both triceps jerks obtained, wrist jerks not obtainable; knee jerks lively, Achilles not obtained; dorsal flexion of all toes on right side, slight

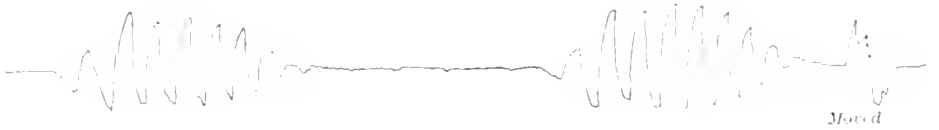

Chart 1.—Tracing from Case I

Babinski on the right side; abdominal reflexes absent, as is true of the cremasterics. No ataxia, but there is an intention tremor brought out when fingers reach their destination. Deep muscular sensibility intact; no astereognosis; no atrophies or deformities; sensation to touch, pain and temperature fairly well preserved. Has cold clammy, cyanotic hands and feet.

Heart, negative, except for a distinct hypertrophy to the left, and an accentuated second aortic. Blood examination normal; urine showed all the evidences of a chronic interstitial nephritis. While at the hospital patient gradually became very restless and stuporous, not recognizing anyone about him; an intense grade of cyanosis developed in all limbs, at times almost black; often had convulsive twitchings of muscles of the right limbs. The respirations remained of the Cheyne-Stokes type until death, a month after admission. Unfortunately no autopsy was performed, but judging from the clinical findings, as compared to the next case, this patient probably had pontomedullary softening resulting from cerebral lues, and a chronic diffuse nephritis.

Case II.—I. C., aged 40, born in Russia; admitted to the Montefiore Home June 4, 1911. Family history is of no importance. Previous history, little obtainable; met with an accident at about 10; he fell into a pond and was almost drowned. Served in the Russian Army for five years, married at 25; wife aborted the first pregnancy in the eighth month, and the third in the fifth month; gave birth to nine normal children, of which eight are well. Patient used very little alcohol, tea, or coffee; always lived under adverse hygienic surroundings.

Present illness commenced three years ago, not preceded by any prodromata. One day, while at work, he was taken with violent trembling of his right arm and leg; no loss of consciousness at the time; the right side of face did not participate in the tremor; no impairment of speech and no disturbance of vision; no headache or vomiting. He returned home without any assistance, but was dragging his right leg, limping considerably. His taking to bed did not check the tremor, and soon it became evident that he could not move the right limbs at all. He remained in bed for two months, continually presenting the mentioned trembling which he could somewhat control by placing the limbs in a certain position. His condition improved, so that at the end of three months following the onset power returned in right limbs; he returned to work, remaining at it for the following two years as efficiently as ever before. His physician diagnosed the case as one of apoplexy. Ten months ago, after a hard day's work, he complained of pain and weakness in right limbs, in which the power gradually diminished; for the next five months he was treated with massage and electricity, and improved slightly. During the ten months following the second onset of his disease he has not complained of headache, pain, or vertigo; no vomiting, dyspnea, or loss of consciousness; no visual disturbances, but there was a marked change in his disposition; he became very irritable and nervous, and would often strike his children on the slightest provocation. Two weeks ago he was aroused from his sleep by a severe dyspnea; a warm drink relieved this somewhat, but there soon followed a paroxysm of cough and sanguineous expectoration, the latter persisting for several days; for some time he was unable to assume the reclining posture because of the dyspnea and cough; he was put on a chair for nearly a week, but finally became too feeble to sit up, and was placed in bed seven days ago; the dyspnea continued to grow worse, he could not sleep nor chew any food, and was in a semi-stuporous condition; three days ago incontinence of urine developed but not of feces. Did not lose consciousness, and two days ago could still speak distinctly and rationally, recognizing people about him. His wife states that when she parted from him a day before admission to this institution he cried, shook her hand, and bid her good-bye.

The striking feature is the presence of typical Cheyne-Stokes respiration, the periods of dyspnea and apnea each lasting 35 seconds (see Tracing 2). The number of respirations during the dyspneic period is 47; during the apneic period the pulse is somewhat slower in rate and the pupils are equal and contracted, whereas during the dyspneic one the pupils dilate and contract alternately (hippus). Another interesting feature is the occurrence of unconsciousness during the apneic phase; he cannot hear anything said to him. There is some cyanosis of the face and extremities, this being pres-

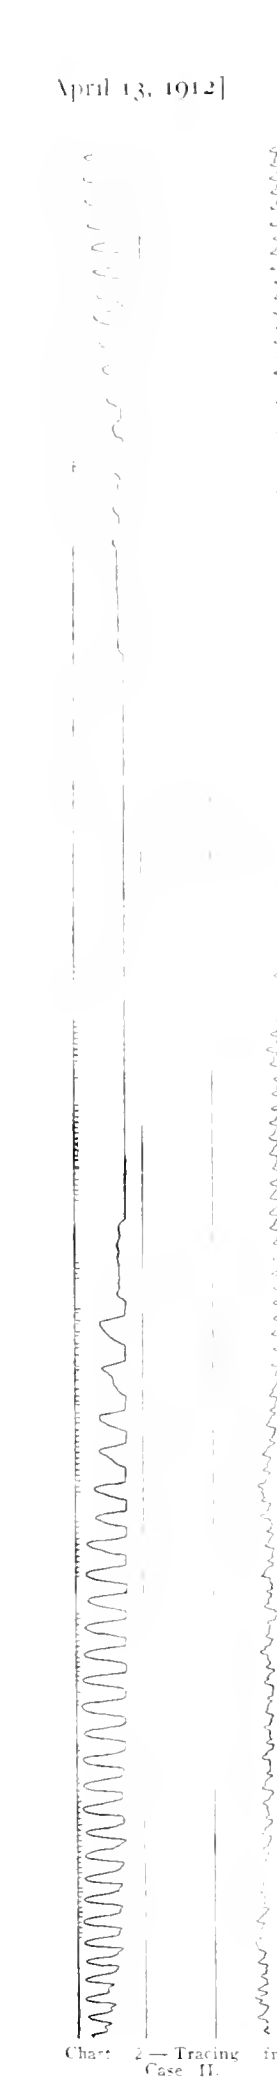

Chart 2.—Tracing from Case II.

out all the time. Speech is thick and indistinct on observation. Head is of normal shape and contour, no tenderness over any part of skull. Pupils are unequal in size, the right being larger, irregular in outline, react to light and accommodation; nystagmus is only present during the apneic period; there is a weakness of both external recti, more so of the right; exophthalmos of both eyes; some ptosis of lids. No involvement of the fifth cranial nerve; marked incapacity of facial innervation, being weaker in the three branches on the right side. Tongue: Cannot be protruded beyond the margin of the lips, deviates toward the right side, is dry and coated. Mouth is continually kept open, lips are cyanotic. Neck: Marked pulsation of jugular vessels on the right side, less so on the left. Chest is emphysematous in type, symmetrical, both supraclavicular fossæ depressed, the right more so. Breathing is stertorous abdominal in type and irregular (see above). Percussion of lungs hyperresonant throughout except for dullness over the right apex; on palpation the wheezing râles are felt everywhere. Auscultation reveals a typical emphysematous condition of both lungs; high pitched wheezing rhonchi all over, prolonged expiration, and a few moist râles over both bases posteriorly. Heart: Apex beat visible and palpable in the fourth interspace, 4 inches to left of midline; on percussion a moderate enlargement of the heart to the left is made out. Sounds are normal all over; heart action more rapid during the period of dyspnea. Pulses are equal in time of appearances, but the left radial is palpated more distinctly; not regular in rate or rhythm, occasional drop-beats. Tension is increased, arterial sclerosis moderate.

Liver palpable 2 inches below free costal border; spleen just felt. Extremities are cyanotic; slight edema of the right ankle. Sensation cannot be tested owing to stuporous condition of patient. Abdominal reflexes not obtained, cremasteric present, a pseudo-Babinski present on both sides; all deep reflexes exaggerated on the right side; left knee jerk increased. Inexhaustible ankle clonus on the right side, none on the left. Gordon and Oppenheim on the left side, no Mendel.

There is a paresis of the right limbs, the lower member more affected than the upper. No trophic disturbances. Deglutition: Patient cannot swallow any solid food, and liquid food only with difficulty. Fundi show congenital medullation of fibers, but no swelling of discs. Urine shows the presence of albumin, hyalin, and granular casts; specific gravity 1.020, excess of indican.

Wassermann reaction is strongly positive. Hb. 90 per cent., R.B.C. 4,800,000, W.B.C. 10,000. Differential count normal. Marked polychromatophilia and granular degeneration of the red cells. A lumbar puncture was performed and fluid was under a very great pressure. Patient died four days after admission, the antemortem temperature being 105.6° F.

Autopsy Findings.—Brain was only organ obtainable. It was rather large in size; convolutions and sulci well developed; veins distended; pia adherent in anterior fossa; basilar vessels sclerotic, with patches of calcification, especially in the vertebrals; cerebellar vessels also tortuous and sclerosed. On sectioning the pons at the level of exit of the fifth cranial nerve a patch of softening is found (Fig. 1); this patch has an irregular shape and extends on either side of the median raphe, but especially to the right anteriorly. The lesion, although greatest at this level, extends throughout the pons lengthwise, measuring about two centimeters; in places the edges are pigmented, brown in color, resembling the remains of an old hemorrhage; above, the degeneration begins at the level of the substantia nigra, and extends in an irregular manner to the junction of pons and medulla below. The meninges are apparently normal; the basal vessels on cross-section are thickened, sclerotic, and slightly tortuous; no thrombosis seen in any of the larger vessels. Numerous areas of softening were likewise found in various situations in the cerebrum, especially on the right side, in the white matter of the internal and external capsules, and in the posterior portion of the left optic thalamus. These areas are about the size of a millet seed, a few of them slightly larger.

Microscopical Examination.—Section of pons at level of most extensive softening was made, *e.g.* level of exit of the fifth cranial nerve and the following picture was present: The arteries are all greatly thickened, lumen narrowed; this process involves both the muscularis and the intima, *e.g.* hypertrophy of the muscular layer and a fibrous condition of the intima; in many the lumen is practically gone. The small arterioles are surrounded by an extensive area of round cell infiltration while the large vessels have a clear zone surrounding them, being separated from the brain substance. The areas of degeneration are numerous, some being very minute; at one situation there is a small hemorrhage which on serial section was found to originate in a plugged arteriole. The areas of softening consist of detritus, fibrillæ, and large epithelial-like cells; the walls of these areas are composed of many small round cells. Similar pictures were found in optic and thalami.

It is manifest that the condition primarily is a diffuse arteritis, probably of syphilitic origin, sec-

ondarily leading to thrombosis of the finer vessels with subsequent hemorrhage and softening. The lesion is most marked in the pons (see Fig. 3), but extends throughout the entire brain, mainly, however, in the white matter.

We are greatly indebted to Dr. S. Wachsmann, Medical Director of the Montefiore Home, for his kind assistance and for permission to publish the above cases.

3390 Broadway.

EXTENSION AND RECURRENCE OF BREAST CANCER THROUGH THE DEEP FASCIA.

By LEIGH F. WATSON, M.D.,

Oklahoma City.

The frequency of malignancy in tumors of the breast makes their early recognition and diagnosis a subject of paramount importance to both the general practitioner and the surgeon. When it is realized by the family physician and patient that thirteen out of every fourteen breast tumors in women over forty are malignant and one half of the benign growths ultimately become malignant the urgency for an early diagnosis and thorough surgical treatment is apparent.

It is the duty of the profession to impress on women the necessity for a prompt consultation with the family physician on the first appearance of a tumor or growth in the breast, however small or apparently insignificant it may appear to be; therein lies the only hope for a cure and the prevention of metastatic extension of the disease. Pilcher says it cannot be too strongly emphasized that practically every case of carcinoma of the breast, when it has reached the degree of development by which a palpable tumor is formed, is already in an advanced stage, such an advanced stage that, as a rule, metastatic deposits have already begun to be formed. Unfortunately the diagnostic signs that we are taught to associate with cancer are really its complications; when the classical symptoms are sufficient to make a positive diagnosis the case is incurable with the most radical operation.

As with cancer in other parts of the body, breast cancer is at first local and curable. The fact that many cases even though operated upon finally succumb is a factor that will continue to deter a certain class of patients from seeking medical advise at the earliest and most favorable period. These patients will seek an early operation only when the family physician impresses on their mind the favorable results obtainable with the early operation and that the operation itself is practically free from danger when performed early.

Cancer of the breast is more frequent in middle and old age because of the senility and lack of tissue resistance. In the young the liability is much less, but when it appears in youth the growth is more rapid and metastasis occurs earlier.

Richardson writes, "the more I consider the question of reasonable accuracy in the diagnosis of breast tumors, and the larger my experience becomes, the more I am inclined to advise operation on all breast tumors, whether the diagnosis points to malignancy or not, provided the patient is of the cancer age."

Bloodgood says that 31.5 per cent. of the breast tumors in the surgical clinic of Halsted at the Johns Hopkins Hospital were benign—among these benign lesions 25 per cent. were simple cysts, 5 per cent. papillomatous cysts, and 1 per cent. galactocele. Over 30 per cent., therefore, of benign lesions are cystic. With but few exceptions cysts appear during the cancer age. Among the carcinomas, about 25 per cent. are cysts, about equally divided between cancer cysts and the malignant papillomatous cysts. To about every 100 benign cysts there are about 25 malignant. In 604 mammary neoplasms at the Johns Hopkins Hospital 1.5 per cent. were sarcomas

In an analysis of 5,000 cases from the German clinics by Rodman, 20.5 per cent. occurred under 40 years, 9 per cent. between 20 and 30, and 5 per cent. between 30 and 40. The period of greatest liability is about and after the climacteric, when the gland is undergoing functional decline and its epithelial elements are prone to proliferate unduly. This should be kept constantly in mind because an involution mastitis, the condition most difficult to differentiate from carcinoma, is also likely to occur about the menopause. While cancer may, and does at times, affect all parts of the breast, it is more frequently found in the axillary hemisphere than in the sternal half of the gland; and of the two outer quadrants the upper is more frequently involved than the lower. Next in point of frequency, the middle portion of the gland—directly behind the areola—will be involved. It is the latter variety of tumors that by their adhesions to neighboring structures pull on and cause retraction of the nipple. Benign tumors and sarcoma, on the contrary, are more frequently met in the sternal hemisphere, the upper and inner quadrant particularly.

Carcinoma hardly ever occurs before puberty, sarcoma is also rare in children. Both are more frequent in girls than boys.

Handley claims that cancer recurs in the fascia and not in the skin and many cases of recurrence are due to neglect of the surgeon to remove the deep fascia over the ribs, clavicle, and sternum. Cancer extends through the lymphatics and not through the blood stream. The lymphatic distribution of the breast is divided into six distinct groups. The earliest extension occurs in the axillary region. Second in the neck; here extension occurs through the fascia and lymphatics over the clavicle as well as under it. Third through the lymphatics that return with the anterior intercostal vessels to the anterior mediastinal glands; these glands drain the inner side of the breast. Fourth, extension to the posterior group of glands that receives the lymphatics of the internal intercostal muscle. This is the route of extension that occurs when the tumor is fixed to the chest wall and the prognosis is practically hopeless as regards a cure. Fifth, across the sternum to the other breast. Cases rarely occur with cancer involving both breasts. Sixth, down the epigastric fascia and into the abdomen between the recti and digitations of the external oblique.

Horsley states that pain is more likely to be present in a benign growth than in cancer, though it is not often encountered in any tumor of the breast in the early stages. Pain is usually present in inflammatory rather than malignant disease.

Chronic or involution mastitis, adenoma, and the several varieties of cysts are the diseases most frequently encountered in the breast that may mask the diagnosis of malignancy, but when it is remembered that one-half of these benign conditions tend to become malignant it is evident that all tumors of the breast the nature of which is doubtful should

be removed. Every tumor of the breast should be considered malignant until its innocence is proved. As a rule, the nipple of the affected breast is on a higher level than the nipple of the healthy breast, owing to a shortening of the trabeculæ. The nipple of a breast containing a benign tumor on the other hand will be found to be lower than the nipple of the healthy breast.

Early operations on patients in middle or advanced life are favorable. The younger the patient the worse the prognosis. Meyer says, with the radical operation in the hands of all surgeons, no matter in which direction we advance in operating, between 40 and 50 per cent. of the patients operated on pass the three-year mark; between 30 and 40 pass the five-year mark. Rodman believes operation in the first year should yield 75 per cent. of cures. Cheyne reports 50 per cent. of cures. At the Johns Hopkins Hospital there were only 43 per cent. of cases living three years following the radical Halsted operation where there was no axillary involvement; of the cases with axillary involvement only 25 per cent. survived the three-year limit; while of those with cervical involvement only 7 per cent. lived over three years.

Jacobson says the importance of removing all of the retromammary tissue, pectoral and axillary fascia, and the axillary fat and glands, along with the breast, in all cases of carcinoma, cannot be too strongly insisted upon or too often repeated. The anastomoses and intersections of the lymphatics are so free that it is impossible to say toward which set of glands the lymph from any given point in the breast will be conveyed.

Butlin states that when the supraclavicular glands are cancerous a case is hopeless so far as a radical cure is concerned. Recurrences usually come within the first, occasionally in the second, and infrequently in the third year.

Stiles believes local recurrence of cancer after removal of the breast is usually due, not to the rest of the breast being in a precancerous state, but to the non-removal of small and often microscopic foci of cancer, more or less remote from the main tumor, and depending for their origin upon the rest and growth of cancerous emboli disseminated more or less directly from the primary tumor along the lymphatics.

When recurrence appears it is evident that the disease was more extensive than was apparent at the first operation; especially discreditable to the operator is reappearance of the cancer *in situ*; to avoid this risk the whole of the skin, breast, tissue, fat, and fascia over the affected breast should be removed, regardless of the earliness of operation and smallness and mobility of the growth.

An operation is contraindicated in cases that present extensive infiltration of the skin with shot-like nodules, commonly seen after osteopathic treatment; in Hutchinson's "cancer erythema"; in *peau d'orange*, a brawny leather-like condition of the skin; in the presence of visceral deposits; with infiltration of the supraclavicular or cervical glands; involvement of the axillary vessels and nerves positively contraindicate operation.

A secondary operation should be performed when the recurrence is in the form of small nodes in the skin incision or axilla and in those cases when the radical operation was not performed the first time. Even then the chance for a recovery is very remote, for, as Cheyne says, "the patient's chance lies in the first operation."

Severe pain from involvement of the brachial plexus is fortunately a rare complication; when this occurs Jacobson advises dissecting out the subclavian triangle and removing the enlarged glands that will be found to be pressing on the nerve trunks. Swelling and edema of the arm in cases that are inoperable can usually be relieved by elevating the limb at night and the constant wearing of a snug fitting bandage or elastic support.

Pain and swelling of the arm of the affected side in inoperable carcinoma can often be relieved by Handley's operation, which consists of passing several buried silk threads beneath the skin from the shoulder down into the arm. A longitudinal incision is also made and a roll of ten or twelve threads buried in the incision and the wound closed. His object is to form new lymphatic channels and thereby relieve the obstruction of the lymph flow.

In selected cases local anesthesia can be successfully employed for amputation of the breast; in the presence of malignancy and axillary involvement it is contraindicated. In simple mastitis and adenoma local anesthesia is sufficient. Massive infiltration is the best method for blocking the anterior thoracic nerves. Hirschel outlines the field with a series of ten injections of the anesthetic, pointing the needle in four directions to spread the fluid. The first puncture of the needle in the axilla is the only one that is painful, the others being all at previously anesthetized points. He reports several hundred operations successfully performed on the thorax under local anesthesia.

One of the most satisfactory operations is to remove the breast tissues, fat, and fascia with a circular incision. Pads wrung out of hot saline solution are applied to the raw surface as rapidly as the breast structures are removed; with this method the bleeding is insignificant and, as Bodine has demonstrated, is easily controlled with four hemostats. The incision is now prolonged upward and outward along the arm following the line of curvature of the first incision. Dissect up the skin flaps freely around the entire wound by sharp dissection, then free the under surface of the pectoralis major and divide the muscle in the center. Dissect up the humeral head of the pectoralis major and cut off close. Dissect free the under surface of the pectoralis minor and cut in the center; this exposes the axillary vein. Carefully remove all glands in the axilla and along the axillary vessels and excise all fat and fascia possible. Cut the pectoralis minor close to its humeral attachment and remove the costal attachments of both muscles along with their sheaths and the origin of the pectoralis major from the sheath of the rectus. According to Handley, cancer enters the abdomen through the fascia between the recti. Make an incision extending up over the clavicle for the removal of the supraclavicular fascia. Always remove all of the fascia. Handley writes, "the aim should be to remove as widely as is practicable a circular area of deep fascia with its center at the primary growth, remembering, however, that growth extends in the fascia more readily in a vertical than in a horizontal direction. The use of the expression 'removal of the pectoral fascia,' instead of 'removal of as wide an area as possible of the deep fascia,' and the exclusive attention paid to the axillary glands as the channels of dissemination, have led to the neglect in the incision of the deep fascia over the lower part of the thorax and the upper part of the abdomen. It seems to be in this direction that the scope of the

operation needs extension, rather than in the direction of opening up the posterior triangle. The distance from the nipple to the clavicle may be taken as the radius of the circle of deep fascia round the growth, which can be removed without difficulty by undermining the skin flaps sufficiently. If the growth starts under the nipple the deep fascia should accordingly be removed—above, up to the clavicle; internally, one to two inches beyond the median line; externally, just beyond the edge of the latissimus dorsi; below, to a horizontal line running at least two inches below the tip of the ensiform cartilage. If the growth is in the lower and inner part of the breast the circle of infected deep fascia will encroach still more on the surface of the abdomen, over the opposite side of the breast, and the removal of the deep fascia in these directions must be carried out yet more widely."

Control oozing with pads wrung out of hot saline solution and dry the wound carefully. Dawbarn advocates the use of boiling water to be applied to the raw surface for a few moments; this effectually seals all lymphatics and speedily stops all oozing of blood. Introduce a gutta percha drain through a skin puncture at the lowest point of the axillary wound. Close the wound, using tension sutures as required. Finally, apply a large gauze dressing and Bodine's triangular splint. This splint affords the patient the greatest amount of comfort, prevents scar formation with limitation of movement of arm on affected side, and when it is removed at the end of a week the patient is able to comb her hair. This disability when present is due to cicatricial contraction and not to loss of the pectoral muscles.

[illegible] Building.

MALIGNANT TUMORS.

By L. M. STROUD, M.D.,

TERRELL, TEXAS.

The hypothesis that degenerate cells reproduced by diseased cells, through a long line of ancestry, will, I think, harmonize the theories of Cohnheim and Ribbert. Cohnheim's conception of embryonic cells, out of time and place, held favor with pathologists for a quarter of a century. Ribbert's theory is still more subtle; accepting as he does Cohnheim's hypothesis in part, he predicates his theory upon a theory of cell disassociation, a removal of the normal restraint of neighboring cells of the same tissue or different tissues, but does not admit a primal cause of the inherent proliferative capabilities of degenerate cells through a long line of ancestry to reproduce themselves. His hypothesis is far reaching enough to explain the recognized influence of trauma, age, sex, etc., as exciting causes, but has the fatal defect of not admitting that diseased cells of the body reproduce themselves by proliferation with increased morbidity, if impressed by the same diseases for a number of generations. The proposed hypothesis of degenerate cells transmitted through a long line of ancestry with an increased proliferative morbidity through degenerate gemmules causing malignant tumors, will correllate the proliferative theory of Cohnheim and the disassociation of cell life of Ribbert and admit all the recognized data of age, trauma, etc., as exciting causes. If the hypothesis which I propose will not stand the searchlight of science, the pathologists of the future must still hunt for the cause of malignant tumors.

To understand this subject better it is necessary to contemplate the modifications of reproductive gemmules in their histological makeup of the tissues of the organs of the individual through a long line of ancestry. In the lower animals where man has control this can best be exemplified. If puppies' tails are lopped off for four generations the gemmules of their caudal appendages are not reproduced and so they come stump-tailed. The untrained mind of the peasant is familiar with the form, size, and qualities produced in domestic animals through a long line of ancestry. The Jersey cow, for instance, has been developed for her milk qualities; the milk gemmules in her udder causing so much rich milk, have not been produced in one generation, but likely it has taken a thousand. It took England four hundred years to produce the beef Durham, giving him form, size, and beef qualities. This has been done through a line of ancestry stimulating the reproductive gemmules of the muscles. The large Durham cow is, however, such a poor milker that occasionally she will starve a calf to death. The reproductive gemmules in the udder have not been cultivated. Take, for instance, a little Spanish paint mare with red and white spots all over her, a glass eye, piebald, and stocking-legged; when she is crossed with a thoroughbred the colts will show a Spanish mark for sixteen generations, some will have a glass eye, others a paint spot, a blazed face or a stocking-leg, etc., and they will all partake of her wild nature, but after the sixteenth cross with thoroughbreds all the attributes of the Spanish are lost and the colts are called fullbloods. The house cat is the tiger under the control of man and the reproductive gemmules have been so modified by a long line of ancestry that unlike his ferocious prototype of Bengal he has been made the friend and playmate of the babe in the cradle.

The reproductive gemmules of the genus homo are susceptible to modifications through a long line of ancestry as much so as the lower animals, as exemplified by the different races of man. The corpulent man is a product of civilized life and is never seen in wild tribes; wild men are meat eaters, the corpulent man has been produced through a long line of ancestry from overstimulated nutrition by an amylaceous diet. His reproductive gemmules have been so impressed that he transmits these qualities to his offspring.

It is assumed the body is an aggregation of cells, healthy and degenerate, representing the equation of our healthy and diseased ancestry. Our ancestors form the working basis of life expectancy in insurance risks. The American mortuary tables stand exact. Our individuality is more influenced by four generations back of us than by our immediate parents; we represent their strength and weakness, health, disease, etc., through the qualities transmitted to the reproductive cells of the body through a long line of ancestry; we represent the degenerate cells transmitted from generation to generation, from disease, just as we do their healthy gemmules. Children are the legitimate product of their ancestors, both healthy and degenerate, so with the reproduction of the individual cells in their body they represent both healthy and diseased tissues of past generations. The gemmules of reproduction become degenerate from diseased organs through a line of ancestry; for instance, a chronic endometritis with cervical laceration and scar tissue for four generations will doubtless so modify

the reproductive gemmules as to cause degenerative cells in the histological makeup of this organ, and when metabolism is disturbed during the menopause and the harmony of the healthy and diseased cells is disturbed by nutritive changes the degenerate cells become parasites, losing their normal relation with other cells and derive their nutrition as parasites from other tissues, taking on an active embryonic proliferation. It should be remembered that cell proliferation is a normal process of the tissues in all wounds; healthy wounds are repaired by the healthy proliferation of cells, healthy cells proliferating healthy cells in the reparative process. It would be a logical postulate to assume that degenerate cells would reproduce themselves. In chronic inflammation we witness hyperplasia of the thickened tissues by the proliferation of healthy cells, causing a benign tumefaction. The diseased or degenerate cells taking on an active proliferation reproduce themselves in the form of a malignant neoplasm.

These tumors are parasites on the body. We witness the power of the organism to sustain these parasites by the degenerate cells of sarcoma, circulating in the blood currents and lodging as foci, forming multiple malignant tumors through active cell proliferation. The blood is an organized tissue and is capable of reproducing itself through degenerate cells as is exemplified in hemophilia through a long line of ancestry. The leucocytoid cells are degenerates circulating in the blood currents and take part in the formation of scar tissue. It is a curious clinical fact that the degenerate cells seek scar tissue for their development as is exemplified in a uterine carcinoma beginning in the scar tissue of a cervical laceration or an old cicatrix from a mammary abscess; the pyloric cancer from an old gastric ulcer or the scar tissue of the lower rectum from fissure, chronic ulcer, or hemorrhoidal tumors; the disease appearing in the face from a chronic eczema or in the scar tissue of the lip produced by chronic irritation from smoking, or about the gall-bladder and liver from chronic cicatricial tissue, from catarrh, or about the ovary from the cicatrix from a ruptured Graafian follicle, etc.

So if in my contention the postulate has been sustained in the hypothesis that all malignant tumors are due to the proliferation of degenerate cells in their primal origin, the scientific corollary follows that all other causes of malignant tumors are exciting causes only.

The tissues of the body are capable of sustaining parasites in an almost incredible way. We witness this in the form of a partly absorbed twin as an aggregation of cells nourished and sustained by the body. The blood itself is an organized tissue of the body and sustains many cells in the form of parasites, living sarcoma cells, balloon cells found in vesicles of herpes zoster, plasma cells, which are pathogenic, found in various mucous membranes and in lymphoid tissues. These migrating, polyplastic, undifferentiated, degenerate cells, no doubt, in the processes of karyokinesis represent the degenerate reproductive gemmules of our ancestors through a long line of chronic diseases. It is but rational to suppose that a line of ancestry, having premature arteriosclerosis, syphilis, tuberculosis, chronic nephritis, etc., would transmit weakened and diseased gemmules to their offspring and that these cells would become engrafted at suitable sites for their life and proliferation in the form of malignant tumors.

The contributions of exact data through the revelations of the microscope; the mortuary tables of life insurance, exemplifying the exact knowledge of financiers and clinicians, the accepted theories of biologists as to hereditary influence upon cell life modifying the gemmules of reproduction in offspring, the known power of the cells in all inflammatory processes, in efforts at repair to reproduce their prototypes in the formation of tissues as accepted by physiologists and pathologists are the working factors of interpretation entering into the logical postulate in the rationale of this hypothesis.

Since it is an accepted truth that heredity is a potent factor in the production of malignant tumors, and the bacteriologists assure us that the newly born babe has not a living bacterium in it, and pathologists are equally positive that weakened tissues are produced through the diseased gemmules of reproduction through a long line of ancestry, which only need slight exciting causes to produce positive disease, and the microscopist having failed to isolate the specific germ of cancer, the conclusion is almost irresistible that degenerate cells as parasites through primal hereditary tendencies and the exciting causes of age, sex, trauma, or disturbed metabolism from pathogenic bacteria, etc., are the links in the chain of morbid events accounting for the primal origin of malignant tumors.

EFFECT UPON THE EARS OF RAPID TRANSIT THROUGH THE HUDSON AND EAST RIVER TUNNELS.

By EDMUND PRINCE FOWLER, M.D.,

NEW YORK.

It is a common experience for passengers traveling through the submarine tunnels connecting Manhattan Island with New Jersey, and with Long Island, to notice a sensation of blocking of the ears during this part of their journey. Those who have felt the sensation naturally wonder if others are affected likewise, and usually have their curiosity satisfied a moment after the phenomenon occurs by seeing many passengers take hold of their respective noses with thumb and forefinger, forcibly expire into the nose, and thus relieve the disagreeable sensations.

It is apparent that the ears have become blocked by a change in air pressure, but the amount of pressure change, the mechanism by which it is occasioned, and the effect upon the ear, have not been heretofore investigated.

To determine the air pressures, I employed two very accurate and sensitive aneroid barometers, one in the hands of an observer in the forward, and one in the rear car of the train. On several occasions readings were also taken in the interior cars. Eight trips were made, and the barometric pressures noted especially as follows: Before the train started; while moving on the surface, rapidly, and slowly; on entering tunnel; descending; near middle of tunnel; ascending; emerging from tunnel; especially all extreme excursions of the indicator hand at any point of the journey.

The pressure changes varied greatly on different trips, owing mainly to the speed at which the train was traveling. The greater the speed, the greater and the more sudden the barometric fluctuations, and naturally also the effect upon the ears. Briefly, on entering the tube, the air pressure rose quickly, about 1/5 inch of mercury, in the forward car. In

the middle cars less, and in the rear cars usually a still smaller amount, the pressure even being lowered in the latter situation on several occasions. The pressure varied at several points, owing to changes in level, the rate of progress, and the proximity of ventilating shafts. The opening or closing of windows had a marked effect on the air-pressure changes. In the forward car I observed at no time a greater variation than 3/10 inch mercury.

In the rear car more marked changes were noticed, and on two occasions there was a fall of over 4/10 inch mercury within the space of about one second. This occurred on passing one of the exhaust shafts, and was due to the partial vacuum brought about by the combined action of the exhaust shaft and the rapidly moving train. The extreme range of pressures during a trip was equivalent to 7/10 inch mercury. This did not occur suddenly, there being many forward and backward excursions of the dial hand before it was accomplished.

I have given the data as variations, instead of actual readings of the manometer, as the latter would be confusing owing to the differing surface air pressures on the various days, and as it is with the changes, and not the height of the barometric readings with which we are concerned. Some allowance must be made for pressure changes due to the varying grade of the tracks, but this is of but small importance, as the grading is never abrupt, and the rails are more on a level than is generally appreciated.

A change of pressure of ½ inch mercury would, on first thought, appear to be but a trifling variation, but when one considers that it represents a pressure of about ¼ pound to the square inch it is apparent that no inconsiderable factor has to be dealt with.

Such a pressure brought to bear upon the drum membrane of the ear is surely more than enough to occasion symptoms of its presence, when, as I have shown some years ago, a fraction of a millimeter of change in pressure is easily dectected by the ears, not only as a sensation of pressure, but as a distinct inhibition of the acuteness of hearing. This occurs if the pressure is applied upon the external surface of the drum, and within a comparatively short space of time, as otherwise the air pressure in the middle ear will also increase by the way of the Eustachian tube, and the differing pressures on the two sides of the drum membrane will be equalized.

If the walls of the Eustachian tube are abnormally adherent to each other, or if the lumen is stenosed so that the physiological ventilation of the middle ear is prevented, any change in air pressure will be more definitely recognized than it would be otherwise, and the effect on the hearing will be greater. [illegible] in the middle ear [illegible] of changing air pressures [illegible] whether they interfere with [illegible] in reaching the [illegible] wall.

The principal factor to consider among the phenomena under consideration is the suddenness with which the changes occur. If the drum is subjected to lowered pressure the effect upon the ear is more marked than would be an equivalent increased pressure, and for the following reasons: Diminished pressures tend to suck the walls of the Eustachian tube together, whereas increased pressures tend to force them apart. The latter, therefore, tend to facilitate the equalization of pressures upon both sides of the drum membrane, and the former to hinder such equalizations. The greater the suction the closer are the tubal walls drawn together, and the more certain is the communication with the nasopharynx shut off.

As to any detrimental effect upon the auditory apparatus: it is apparent that subjection every day or twice a day to the extreme air pressure changes noted on some of my trips would be injurious, and especially to those suffering from certain tubal and catarrhal troubles. Unless the ear blockage is relieved within a few moments after it occurs, retraction of the drum membrane, and blocking of the tube is accentuated. Especially is this the case if the ears are exposed first to an increase, and then immediately to a sudden diminution in air pressure. (This frequently occurs in tunnel travel.)

To the normal ear no harm should result from air-pressure changes greater even than those experienced in the tunnels, for the voluntarily, or involuntarily excited act of deglutition, quickly relieves the ear block in such cases. Persons in whom the ordinary act of swallowing does not at once relieve the blocking, should consult an otologist, as they have received a significant warning that all is not right with their auditory apparatus.

In many cases instant relief and protection from future trouble may be obtained by simple means. The common practice of forcibly blowing into the nose (Valsalva's experiment) may work great harm, as it is wholly unphysiological and dangerous.

In suitable cases the author's method of middle ear inflation is all that may be required, and I recommend it for this purpose, not only because of its efficiency, but because it is always at hand. It is executed as follows: While the nostrils are tightly closed by pinching them together with the thumb and forefinger as near their free borders as is possible, gently increase the air pressure in the nose and nasopharynx by attempting to expire wholly through the nose, and, while maintaining this increased pressure, swallow. The result will be the inflation of both middle ears. This is brought about by the opening of the tubes during the increased nasopharyngeal air pressure, due to the patient's efforts and to the ascent of the soft palate. During the second stage of deglutition a negative pressure is avoided, because the primary increase in pressure and the bulging of the elastic lateral walls of the nose supply a sufficient amount of air reserve to enable the descent of the soft palate to occur without creating a partial vacuum in the nasopharynx. Until familiar with this method of inflation it is well to take a full breath preliminary to its performance. No instruments are required for its performance, and anyone with ordinary muscular control can easily learn to inflate the ear safely by this method.

616 Madison Avenue.

Observations and Experiments on Typhoid Fever.—A. Marrassini has studied the blood and feces of seventy patients suffering from typhoid or paratyphoid fever. He found in the feces a large number of forms intermediate between the typhoid bacillus and *Bacillus coli*. He also found at various periods of the disease in the same individual different types of microorganisms. It is suggested that from various influences or spontaneously there may occur a gradual transformation from one type of microorganism into another.—*Pathologica*.

RECENT STUDIES ON THE NATURE OF MEASLES AND ON ITS EARLIER DIAGNOSIS.

THE widespread prevalence of measles, particularly at the present time, its persistently high mortality, and the frequency with which it leaves its victims a prey to other diseases, impart considerable interest to the investigations that have been conducted to determine the nature of this disease, and to the hypotheses that have been advanced as to its causation. The recent results accomplished by American laboratory workers in the inoculation of monkeys with this disease, has strengthened the belief in its bacterial origin, but this belief has never been confirmed by the actual demonstraton of the causative microorganism. The nearest approach to this demonstration was attained in 1903 by C. Giarrè and L. Picchi (*Lo Sperimentale*, 1903, Vol. 57), who isolated from the mucous membranes of patients ill with measles a microorganism which they designated the *Bacillus hemophilus*, which was not indistinguishable from the influenza bacillus, which could not be cultivated without the presence of hemoglobin in the culture medium, and which four years later Giarrè and Carlini isolated from the blood of the majority of cases of measles which they examined. But no etiological relationship between this microorganism and measles was established. In fact the former was found to exist among the bacterial flora present in the bronchial secretions of bronchitis, bronchopneumonia, and other infectious diseases.

Of more immediate importance than the actual isolation of the microorganism of measles is an improvement in the methods of prophylaxis. Belief in the aerial transmission of this disease has been gradually supplanted by that of contact infection, nevertheless in spite of the vigilance of health and school authorities there seems to be no diminution in the prevalence of measles. The essentials of efficient prophylaxis are early diagnosis and prompt isolation. Unfortunately the diagnosis of any individual case is not made until in many instances the infection has already been transmitted to others. The detection of the buccal spots enables one to make a diagnosis several days before the exanthem appears, but even this may be too late for efficient prophylaxis. Of greater value, particularly in the case of schools and institutions, would be the ability to make a diagnosis of measles during the period of incubation.

That this is possible has been shown by R. Hecker (*Zeitschrift für Kinderheilkunde*, Vol. 2, page 751), as the result of his researches into the cytology of measles. He found that the blood presents characteristic changes even from four to six days before the appearance of Koplik's spots. These changes consist of a distinct leucopenia, a relative and absolute lymphopenia, a shifting to the left of Arneth's blood picture, and a diminution in the number of eosinophiles. The leucopenia is interrupted by a leucocytosis four and a half days before the appearance of the eruption. There is a reversal in the relationship between the lymphocytes and the neutrophiles, the predominance of lymphocytes which is normally characteristic of the blood of the child is replaced by a predominance of the neutrophiles. During the period of incubation of measles, there is thus an extensive destruction of leucocytes, most pronounced in the case of the lymphocytes. The degree of this destruction fluctuates from day to day.

An interesting phenomenon in connection with the cutaneous reaction to tuberculin has been noted by von Pirquet (*Deutsche medizinische Wochenschrift*, 1908, No. 31). Children that ordinarily react positively to the inoculation, lose this power for a period of one week during an attack of measles. This temporary loss of cutaneous hypersusceptibility to tuberculin occurs in no other disease than measles. Hence if a child suspected of having measles gives a positive von Pirquet reaction, the diagnosis of measles may be definitely ruled out. Apparently during measles there is a disappearance of the antibodies which bring about the clinical reaction between tuberculin and the cells. Since the lymphocytes are regarded as being associated with the production of these antibodies, one can readily understand how the disappearance of the latter would go hand in hand with the destruction of the lymphocytes.

In the differential diagnosis between measles and other exanthemata there have been recently added new clinical and laboratory resources. About five years ago Simonini (*Rivista critica di Clinica Medica*, 1907, No. 23) observed that even in the mildest cases of measles there may occur an hepatic insufficiency, which manifests itself in a levulosuria. In severe cases of measles the impairment of liver function results in the excretion in the urine of urobilin, glucose, and an excess of indican. Still more recently Pach and von Reuss (*Zeitschrift für Kinderheilkunde*, Vol. 2, page 400) have noted that whereas urobilinuria occurs in the majority of cases of measles, it is not as pronounced as in scarlet fever, and lasts for a shorter time. Unfortunately for diagnostic purposes this reaction fails during the period of incubation and during the first part of the eruptive stage.

A most ingenious hypothesis as to the nature of measles, and one which nicely fits in with the known facts regarding this disease, has been advanced by Sittler in the *Münchener medizinische Wochenschrift*, 1909, No. 52. He believes that it is not improbable that the manifestations of measles represent the reaction of hypersusceptibility to a foreign body or toxin, analogous to the phenomena of serum sickness. He also believes that the toxin is set free by a *Staphylococcus albus* which is present

in the secretions of the respiratory tract of the infected individual. Thus the symptoms of measles which bear many points in common with those of serum sickness are regarded by Sittler as manifestations of anaphylaxis. In support of this view may be cited a number of observations recently recorded as to the occurrence of measles relapses. There has been little question that a child may pass through two or even more attacks of measles, but little has been known regarding true relapses, that is, attacks following one another at short intervals. In the *Archiv für Kinderheilkunde*, December 23, 1911, Feibelmann, in reporting a case in which there were three unmistakable attacks following one another at intervals of ten and nineteen days, respectively, presents a review of the five other instances reported in the literature of single or double relapses. He concludes from his analysis of these cases that it is impossible to decide whether the measles relapse represents a recrudescence of the original infection or an entirely new infection, and whether the immunity conferred by one attack is but of temporary duration. On the other hand, F. Corominas in the *Revista de Ciencias Medicas de Barcelona*, October, 1909, advances a plausible explanation of these relapses on the basis of anaphylaxis. The text of his study was furnished by three cases of measles that he observed about the same time in one family, of which cases two suffered relapses four and five weeks, respectively, after the primary attack. He believes that in these and in similar instances reinfection occurs during a period of anaphylaxis that persists for two months after an attack of measles, and that for this reason the individual convalescent from an attack of measles should be carefully guarded during this period from further infection. In support of his hypothesis, Corominas cites the fact that in all diseases in which immunity is produced there is a preliminary period of immunity.

MENTAL DEFECTIVES AMONG IMMIGRANTS.

THERE is no doubt that the most important feature of the inspection of immigrants is the medical examination. No matter how well qualified for entrance an alien may be in other particulars if he lacks proper physical condition he is undesirable. Of the various medical defects which the law properly aims to detect, certainly none is of more vital importance to the country at large than mental defects. The increasing recognition of this fact is evidenced by the popular agitation in newspapers and magazines looking toward more careful exclusion of mental defectives. The same interest is shown in current medical literature.

New York State is most vitally concerned in this question, as is well shown by T. W. Salmon[1] of the State Board of Alienists, since it receives 26 per cent. of the total immigration into the United States and is the destination of more than 80 per cent. of immigrants found on arrival to be insane or mentally defective. In the New York State hospitals there are more than 8,000 alien patients. Practically all of these enter through Ellis Island, hence the inspection at Ellis Island represents the essential line of defense against the incoming stream of mental defectives. The inspection here must of necessity be cursory and incomplete at present because of the lack of men and facilities available for the work. The incoming immigrants at the Island are sent down two parallel lines in single file. Each line makes a right-angled turn midway in its course. At this turn stands a medical officer who looks over each immigrant from the front, side, and rear as he passes and turns. At the end of the line a second medical officer examines eyes alone. All who present any evident defect or anything arousing suspicion are turned aside into the medical detention rooms for more careful examination.

Thus it is evident that the only chance to detect a mental defective is afforded as the immigrants pass in line before the medical officer. Under these circumstances it is small wonder indeed that so many feeble-minded children and insane adults escape detection. Diagnosis of mental disorder rests very largely on the conversation of the suspect. It is useless to expect a medical examiner to do effective work in this regard when he cannot even converse with the great majority of those he is examining, not knowing their language. As it is, having marked certain mental suspects on the line, he has an opportunity for more detailed mental examination through an interpreter in the medical detention rooms. But even here interpreters are not numerous enough and the same difficulty is met with in the immigrant hospital where mental cases are held for observation pending a careful diagnosis. It is easy to recommend sweeping and impracticable changes. To do so is to make a bad situation worse. But a perfectly feasible improvement, entirely aside from the difficulty of securing more medical officers and better facilities for their work is to supply more interpreters who should be detailed to the medical division exclusively. Interpreters should stand beside the first medical officer on the line inspection so that any or every immigrant as he passes through may be questioned in his own language. By this procedure alone, the chances of detecting insanity and feeble-mindedness would be enormously increased. More interpreters in the medical examining rooms and in the immigrant hospital would be equally valuable.

There is no question as to the great and increasing importance of detecting and excluding mental defectives among incoming aliens and the adoption of the suggestion here made would strongly aid in this object.

[1] Salmon, T. W.: "Insanity and the Immigration Law," N. Y. State Hosp. Bull., Nov., 1911.

EUGENICS AND GEOGRAPHY.

IN studying the geographical distribution of insanity in Massachusetts during the decade from 1901 to 1910, as determined by the number of commitments to the hospitals for the insane, E. E. Southard (*Boston Medical and Surgical Journal*, March 28, 1912), has reached a number of interesting conclusions. He has found that the Berkshire hills and some of the islands of Massachusetts contain a group of twelve towns which have a zero

rate of insanity production for this period. The towns with the highest commitment rates are largely grouped in the interior of the State and are neither west of the Connecticut River in the higher hill region nor on the seacoast. The census statistics of 1905 have shown that the towns that yielded the largest number of insane also had the greatest number of paupers and criminals, and gave greater evidence of the prevalence of disease.

Using these statistical findings as a basis for his study, the author applies to the two kinds of localities which are characterized by the favorable or unfavorable conditions as regards degeneracy, the terms "eugenic" and "cacogenic." The "eugenic" area of a state or country is one in which the forces of heredity are operating to produce a better human stock, or one in which the hereditary forces are engaged merely in the prevention of deterioration. A "cacogenic" area is one in which hereditary forces are instrumental in bringing about a social decline. The "eugenic" towns are those in which as a whole there are fewest social defectives, while in the "cacogenic" towns the general medical and social status is the worst. In comparing the twelve towns belonging to the former group with twelve belonging to the latter group, the author notes that the total population of the "eugenic" towns is far smaller than that of the "cacogenic" towns. The eugenic group has, however, a somewhat higher percentage of native-born parents, and a still higher percentage of native-born grandparents.

The significance of these studies lies largely in the emphasis they place on the fact that mental degeneracy is closely allied to physical deterioration, and that the stability of population tends to favor its mental and social superiority. If an "eugenic" program ("that extreme eugenic program which seeks to produce more and greater great men for the world by more effective mating") is to be carried out by society, then, as suggested by Sidgwick, intensive locality-studies will have to be made, with the collection of social statistics through every public and private channel.

WOMAN'S PLACE IN MEDICINE

It seems to be a common belief that woman's entrance into the field of medicine is of comparatively recent date. When the question of woman's rights is discussed the fair practitioner is frequently pointed out as an example of woman's progressiveness and achievement. The weaker sex has practised the healing art from time immemorial. In a recent work J. J. Walsh pointed out the prominent place achieved by women practitioners in the early days of medicine, and in the *Liverpool Medico-Chirurgical Journal*, March, 1912, H. Drinkwater presents an interesting discourse on this subject.

Hygeia, the goddess of health, was the daughter of Esculapius, the god of medicine. When Greece was at the height of her fame gynecology was almost wholly in the hands of female practitioners. Galen refers to a work on midwifery written by one Cleopatra. Aspasia was a Greek authoress who wrote on diseases of women. In Rome during the first century there were women who achieved distinction either as midwives or as general practitioners. During the Middle Ages women were welcomed into the healing art and in the University of Salerno in Southern Italy there were a number of women who were especially prominent members of the medical faculty.

Coming to more recent times, it is noted that Anna Morandi Mazzolian occupied the chair of anatomy at the University of Bologna about the middle of the eighteenth century. At this time the Italian universities generally admitted women students. Maria Maetellari graduated in medicine at Bologna in 1799 and Maria delle Donne took the medical degree at the same university in 1800. The University of Zurich granted this degree to a woman in 1807 and in 1809 the St. Petersburg Medico-Chirurgical Academy conferred the medical diploma on its first woman graduate. In 1858 Elizabeth Blackwell, an English woman by birth but a resident of America, was graduated from the medical school at Geneva, New York. In Great Britain women have had a hard struggle in obtaining recognition by the medical faculties, but at the present time there are only a few medical schools that are not open to women. In meeting the requirements demanded of medical students the women have done remarkably well and have shown that at least as regards passing examinations they are equal to the men. In July, 1888, of the thirteen women students who took the intermediate examination at London University, twelve passed, seven took honors, and one took honors in three subjects.

SANITARY PROGRESS.

ONE reads with interest in Forster's Life of Charles Dickens, by way of aftermath to the recent Dickens centenary, how in 1842 the great novelist, while traveling in "the States" noted the insanitary conditions of the prisons which he entered; the unhealthful condition of railway and canal boat travel in his day; our overheated houses; our aversion to fresh air; the simply ghastly spitting nuisance among our men, and much else that is most repugnant to our present-day sensibilities. In the intervening seventy years there has been a veritable revolution, at least in hygiene and sanitation, among us. In these regards Dickens would "hardly know us now." His erstwhile caustic pen would to-day simply drip complimentary honey. Especially would he praise our prisons like that recent French visitor, who saw prisoners in the United States better lodged and better fed than the greater part of the working people of France. Though our improvement in all other respects is not equal to that in our prisons, yet we have advanced mightily in decency and in wholesome living conditions. Our railway trains are getting to be quite cleanly, though they still remain deadly stuffy. So few of us travel on canals nowadays that they are not worth taking into account, except by artists and romantic people who like to turn canal boats into house boats. The fresh air propaganda, when it has the hoped for results, will practically turn our homes inside out so far as pure air is concerned. And who dare spit nowadays with the ever watchful sanitary police officer looking for his prey and the dollar fine for each offense a practical certainty, with incarceration a hideous possibility. He were indeed a hardy offender who would spit in the presence of a sign recently displayed: "Don't spit—remember the

Johnstown flood." Times have indeed changed since Dickens made his memorable visit in 1842, and greatly for the better. If they change as much more in the next seventy years we can then begin to consider ourselves a cleanly people.

Return Cases of Scarlet Fever.

Milne's claim that return cases of scarlatina may be prevented by persistent injections of oil of eucalyptus and strong carbolic acid swabbings of the throat has not been endorsed by some pediatrists who have been giving the method a prolonged test. Negative results might doubtless be explained by the persistence of the infecting germ in the nasopharyngeal space and the prolonged interval which may elapse before return cases develop. At a very recent session of the Verein fur innere Medizin und Kinderheilkunde, Berlin (*Munchener medizinische Wochenschrift*, March 12), Baginsky demonstrated forty-five return cases which had developed after at least forty-two days of hospital sojourn. In such cases the other members of the family do not necessarily contract the disease upon the first exposure. As a rule the return cases develop in from three to tendays. Heubner had seen return cases after the first cases had been kept in hospital seventy and eighty days. Return cases are doubtless bound up in the parasitic nature of the disease itself. Philipp thinks that with the same exposure one individual may develop scarlatina, another a streptococcus angina, a third erysipelas, a fourth nephritis, etc. A single family may show a certain incidence of streptococcus diseases. Bagisky stressed the curious fact that scarlatina in a child often kills the cells of the skin. He also stated that he had never been able to eradicate scarlatina from his diphtheria pavilions. There should be special convalescent homes or pavilions for both diseases.

News of the Week.

Tuberculosis Preventorium.—The new buildings at Farmingdale, New Jersey, will be formally opened on April 25 by Governor Woodrow Wilson of New Jersey. The Preventorium has been conducted during the past two years in two small frame houses on the 170-acre farm donated by Mr. Arthur Brisbane, and is the only institution in this country where children from tuberculous families are cared for if it is thought unsafe for them to be at home. It is estimated that there are some 40,000 children living in tuberculous families under improper conditions in New York City. The new buildings, which have cost about $150,000, will greatly increase the capacity of the institution but much additional endowment is needed in order that it may do the best work.

Coiner in Radium.—By the recent purchase of the only two radium mines at Joachimsthal which were owned by private individuals, the Austrian Government has practically cornered the radium market of the world. The purchase price is said to have been about $1,010,000. It is estimated that the two mines will yield annually about 3 grams of radium. Plans are under way for the development of Joachimsthal as a resort for the treatment of disease by radium.

Lord Lister's Will.—The will of the late Lord Lister disposes of an estate valued at $3,308,330. By it Lord Lister gives $50,000 each to the Royal Society, the King Edward Hospital, and the North London University College Hospital on the condition that his name shall not be associated with the bequests. The sum of $100,000 is also bequeathed to the Lister Institute for Preventive Medicine, London.

Famine Relief in China.—The American Red Cross on April 4 cabled through the State Department to Shanghai, China, the additional sum of $10,000 to be used for famine relief, making a total of $115,000 sent by the Red Cross for this purpose since the President issued his appeal to the country last January.

Dentists in the Navy.—The Senate on April 1 passed a bill adding a dental corps to the navy.

Fire in a Hospital.—The quick action of the staff of doctors and nurses at the Sayre Hospital, Mount Vernon, New York, saved the lives of some thirty patients who were in the hospital when a fire broke out at night recently. All of the patients were carried from the building on stretchers and cared for in neighboring houses. The fire was confined to the first floor and basement of the hospital building.

Naval Medical Reserve Corps.—The Senate Navy Committee recently recommended a bill providing for the creation of a naval medical reserve corps, its members to have the rank of lieutenant, junior grade. There are said a few medical editors and other incompetents who were not appointed to the army medical reserve corps who might be utilized in this new branch of the navy.

Measles at Yale.—Because of the danger of an epidemic of measles at some of the smaller dormitories used by the freshmen class at Yale University the University authorities recently sent seventy members of the class to their homes. A number of cases had developed within a very few days of the immediate vicinity of the dormitories.

Wheeler Milk Bill.—Governor Dix on April 2 vetoed the Wheeler milk bill recently passed by the Legislature with the following comment: "The amendment proposed by this bill is to the effect that a person who shall sell or exchange, or offer or expose for sale or exchange any milk actually produced by a cow or dairy, which is a fair sample of the milk produced daily by such cow or dairy, and to which nothing has been added and from which nothing has been taken, shall not be guilty of any crime on account thereof. Such a provision would be a long step backward in the fight for pure milk, and I think must have been adopted by the Legislature under misapprehension." The bill had met with great opposition among those especially interested in the milk supply of New York City.

Smallpox Quarantine Abolished.—The Utah State Board of Health has issued an order abolishing quarantine against smallpox. Houses in which smallpox patients are under treatment are to be marked with a flag, but its other inmates are to be allowed to move about freely. It is maintained that quarantine against the disease is ineffective and harmful in so far as it gives the public a false sense of security, discouraging resort to actual preventives.

Clerical Healers.—Some months ago in England a committee, of which the Dean of Westminster was chairman, was appointed to report upon the faith healing movement in all its aspects, with particular attention to the matter of obtaining closer cooperation between physicians and clergymen. The report recently made states that there is opportunity for cooperation between the two professions within clearly defined limits, "with a view to the alleviation of physical suffering through the mental or spiritual condition of the patient," but, con-

sidering the question from a standpoint rather unusual in these days, it adds the warning "that any attempt on the part of the clergy to enter into competition with the medical practitioner by any separate and independent treatment of the sick is to be strongly deprecated, not merely on practical but also on religious grounds. For there is a serious danger lest the association of the ministry should divert attention from the primary purpose of that ministry and prove injurious to individual faith."

Germs in Perspiration.—Somewhat of a sensation was created in Paris last week by Professor Poncet, who read a paper before the Academy of Medicine seeking to prove that the perspiration of tuberculosis patients contains tubercle bacilli. He considered that the sweat was of more moment in the spread of the disease than was sputum, and he urged strict disinfection of the skin as well as of body clothes. The possibility that the bacilli can be excreted by the sweat glands suggests that they may also enter the body through the skin, thus bringing into consideration another portal of entry in this disease. Professor Poncet detailed his experiments, which included making cultures from cotton wool impregnated with the perspiration of consumptives and the demonstration of tubercle bacilli which were pathogenic to guinea-pigs.

Chair of Eugenics.—Cambridge University, England, recently received a gift of $100,000 from an anonymous donor to be used for the endowment of a professorship of eugenics in the University, and for supplementary studies of and experiments in heredity. The new chair is to be called the Balfour Professorship of Genetics, as the donor received his first inspiration from Mr. A. J. Balfour. The offer of a further gift for the equipment of an experimental station at the University for the use of the Balfour professor, if such shall later be deemed desirable, is also made.

Radium in Cancer.—During a visit to the Middlesex Hospital, London, made recently by the Queen of England, Dr. Lazarus Barlow demonstrated to Her Majesty his discovery of radium in the cancer cells. By electrical methods Dr. Barlow claims to have proved both that radium is present, though in minute quantities in carcinomatous and sarcomatous tissues, and that it is absent from normal tissues. At least this is the report brought by cable to the daily papers.

To Vaccinate Regiment.—All of the 800 enlisted men and fifty-two officers in the Fifth New Jersey Regiment, at Paterson, New Jersey, will shortly be vaccinated against typhoid fever, the vaccine being supplied by the Medical Department of the U. S. A.

For Cleaner Cars.—At a meeting of the New York County Homeopathic Society held recently a resolution was adopted protesting against the uncleanliness and disregard for ventilation found in the surface cars in this city. It was voted that the society call the matter to the attention of the Department of Health and of the Public Service Commission.

Pasteur's Birthplace.—The Mayor of Dole, France, has received a gift of $10,000 from Mr. John D. Rockefeller of New York, to be used for the upkeep of the house in which Pasteur was born, in that town.

"Phossy Jaw" Bill.—The United States Senate on April 3 passed the so-called "Phossy jaw" bill, which levies a prohibitive internal revenue tax on matches in the manufacture of which white phosphorus is used. The House had already passed the bill, which was framed to accomplish indirectly what Congress was prevented by constitutional limitations from doing directly, that is, the protection of workmen in match factories against the bone disease known as "phossy jaw," caused by the poisonous fumes of white phosphorus. The manufacture of such matches will be made practically impossible by the levying of the tax. The bill now needs only the President's signature.

Galveston Quarantine Raised.—The national board of health of Mexico at the end of March raised the quarantine against the port of Galveston, Texas, which had been in effect for some time because of the prevalence of meningitis in that city.

Birth Decrease.—A meeting of the Guild of St. Luke, New York City, was devoted recently to a discussion of the decline of the birth rate throughout the country. It was pointed out that this decline was noted chiefly among those classed as Americans, and figures given for New York City showed that if the proportion of births among Italian parents were rated at 46, that among the Jews would be 35, among the Irish 25, and among the Americans 14. This decrease was not, therefore, among the poorer classes of the community, but occurred among the well-to-do, and could not properly be ascribed to economic conditions.

Kelly Memorial.—Friends of the late Dr. A. O. J. Kelly, assistant professor of Clinical Medicine in the University of Pennsylvania, have presented the sum of $1,000 to the trustees of the university as a permanent memorial of Dr. Kelly's services to the university, the income from which is to be given annually as a prize in clinical medicine.

Reciprocity in Medical Licensure in Pennsylvania.—The new Pennsylvania State Board of Medical Education and Licensure has completed an agreement with respect to reciprocity in the matter of license to practise medicine to be offered to other States. On licenses earned by examination reciprocity is to apply only to holders of diplomas from medical colleges recognized as in good standing by the licensing authorities of the State in which the candidate seeks the right to practise; the licensing authorities of either State are to follow the laws of their State in rating preliminary education. A regularly licensed practitioner applying for the benefits of reciprocity must have been in practise at least two years in the State from which he holds his license, but the licensing authorities of either State may in their discretion modify this requirement in any individual case. The applicant shall not have failed in any medical examination conducted by licensing authorities of the State in which he seeks to be licensed, and must appear in person before examiners, present satisfactory evidence of character and that he is not addicted to the intemperate use of drugs or liquors. Credentials as to personal and professional standing shall be required from the medical society of the county or State in which the applicant has been practising.

Dr. John H. Coughlin has been appointed Clinical Professor of Medicine at Fordham University School of Medicine.

Dr. G. A. Bading of Milwaukee, Wis., was elected mayor of that city at the election held on April 2, on the fusion ticket in opposition to the Socialists, who have held office for two years.

Dr. Edward H. Bradford, professor of orthopedics in Harvard University, has been nominated by the Harvard Corporation as the Dean of the

Harvard University Medical School to succeed Dr. Henry A. Christian, resigned.

Dr. George H. Mallett of New York has been appointed gynecologist to the General Memorial Hospital in that city.

Dr. Thomas McCrae of Baltimore was elected by the Board of Trustees of the Jefferson Medical College of Philadelphia on April 4 to fill the chair of medicine in that institution made vacant by the resignation of Dr. James C. Wilson. Dr. McCrae was graduated from the University of Toronto, Medical Department, in 1903, and has been connected with the medical faculty and with the hospital of the Johns Hopkins University since 1906.

Dr. Ernst Lederle, Health Commissioner of New York, recently addressed a large audience of Columbia University on the inspection of food supplies of the city. So far as the question of the milk supply was concerned the Commissioner thought that Pasteurization would undoubtedly prove to be the solution.

Dr. Maurice Victor Silbermark and Dr. Yetta Reissing will represent the Austrian Red Cross Society at the International Conference of Red Cross Societies which will be held in Washington on May 7 to 17. Dr. Silbermark will deliver lectures on the activity of the Austrian Red Cross, both in peace and war, and will demonstrate the latest sanitary appliances and improvements in use by the Austrian society. Dr. Yetta Reissing has been delegated to study and report on sanitary institutions for women.

Dr. John W. Russell has been appointed Medical Superintendent of Matteawan State Hospital, New York, at a salary of $3,500, to succeed Dr. James V. May, who resigned recently to accept the presidency of the State Lunacy Commission. Dr. Russell was formerly first assistant superintendent of the institution, and had been in charge since Dr. May's resignation.

Dr. E. C. Schroeder, head of the agricultural station at Bethesda, Maine, has been sent to Rome, Italy, by Secretary Wilson of the Department of Agriculture, as an official representative of this country at the Seventh International Congress on Tuberculosis, which meets on April 14. Dr. Schroeder has made many observations on the relations of human and bovine tubercle baccilli.

American Urological Association.—At the annual meeting of this association, held in New York City April 2, 3, and 4, 1912, the following officers were elected: *President*, Dr. Granville MacGowan of Los Angeles; *Vice-President*, Dr. J. Bentley Squier, Jr., of New York; *Secretary*, Dr. H. A. Fowler of Washington, D. C.; *Treasurer*, Dr. Homer G. Fuller of Washington, D. C.; *Executive Committee*, Drs. Carl L. Wheeler of Lexington, Ky., Oliver Lyons of Denver, Col., Gustave Kolischer of Chicago, Ill., Walter B. Brouner of New York, and Francis R. Hagner of Washington, D. C.

The Cartwright Lectures.—Professor Ludwig Pick, who holds the chair of pathology in the University of Berlin, has been selected to deliver the Cartwright Lectures of the Association of the Alumni of the College of Physicians and Surgeons for 1912. The lectures will be given on November 7, 8 and 9. Professor Pick numbers among his students many American physicians, all of whom will welcome him to this country.

The Illinois State Medical Society.—The annual meeting will be held in Springfield on May 21, 22, and 23.

The Alabama State Medical Association.—The annual convention will be held in Birmingham on April 16 to 18, under the presidency of Dr. Lewis Morris.

Rocky Mountain Health Association.—Under this title an organization succeeding the Colorado State Association for the Prevention of Tuberculosis filed articles of incorporation in Denver recently. The officers are as follows: *President*, Dr. Sherman G. Benney, Denver; *Vice-Presidents*, G. W. Vallery, Denver, and Dr. R. W. Corwin, Pueblo; *Secretary*, J. Foster Symes, Denver; *Treasurer*, C. S. Haughwout, Denver; *Chairman of Finance Committee*, Thomas Keely, Denver; *Board of Directors*, Dr. O. M. Gilbert, Boulder, and Dr. H. W. Hoagland, Colorado Springs, and the above-named officers. The new organization will retain the affiliation of the old with the American Red Cross and the National Association for the Prevention and Control of Tuberculosis, and will also affiliate with the American Public Health Association.

The New York Society of Anesthetists issues a call to all anesthetists in the United States and Canada to meet in Atlantic City, New Jersey, at the coming session of the American Medical Association, with the idea of forming a national organization. The organization will take place in June 4, at which time officers will be elected and committees appointed to determine the character of the organization. The Secretary of the New York Society is Dr. H. A. Sanders, 864 St. Johns Place, Brooklyn, New York.

Tennessee State Medical Association.—The annual meeting will be held this year at Chattanooga, sessions beginning on April 9.

Pawtucket (Rhode Island) Medical Association.—The annual meeting was held on March 21, when officers were elected as follows: *President*, Dr. J. E. V. Mathieu; *Vice-President*, Dr. Edward S. Kiley; *Secretary*, Dr. Charles H. Holt; *Treasurer*, Dr. James H. Haberlin.

The Clinical Society of the Jewish Maternity Hospital.—At a meeting of this society, held March 27, the following officers were elected for the ensuing year: *President*, Dr. A. Hymanson; *Vice-President*, Dr. Joseph Bakst; *Secretary and Treasurer*, Dr. Alex P. Kaplan. The program for the next meeting, to be held Wednesday evening April 24, will be "Tuberculosis in Infants," by Dr. A. Hymanson; "The Use of Fetal Serum to Cause the Onset of Labor," by Dr. A. J. Rougy.

Southeastern Kansas Medical Society.—The annual convention of this society will be held in Fort Scott on May 9.

American Society of Sanitary and Moral Prophylaxis.—A regular meeting of this society will be held at the New York Academy of Medicine, Thursday, April 11, 1912, at 8.30 P.M. The subject for discussion will be "The Social Evil." Papers will be read by Prof. E. R. A. Seligman of Columbia University, Florence Kelley of the Consumers League, and Dr. Howard A. Kelly of Johns Hopkins University.

North Pacific Surgical Association.—With the object of cultivating the art and science of surgery, uplifting the profession, promoting the highest ethical standards, and deprecating the secret division of fees, an association under this title has been formed in Portland, Ore. Membership will be limited to sixty. The following officers have been chosen: *President*, Dr. K. A. J. Mackenzie of Portland; *Vice-Presidents*, Dr. Meredith Jones of

Victoria, B. C., and Dr. A. C. Sharples of Seattle, Washington; *Secretary-Treasurer*, Dr. Otis B. Wight of Portland.

Obituary Notes.—Dr. ALBERT PLUMMER, formerly of Racine, Wisconsin, a graduate of the Dartmouth Medical School, Hanover, New Hampshire, in 1867, an assistant surgeon in the Tenth New Hampshire Regiment during the Civil War, and a member of the State Legislature in 1882 and 1883, died at the home of his son in Rochester, Minnesota, on March 23, aged 72 years.

Dr. T. J. MITCHELL of Griffin, Ga., a graduate of the Atlanta Medical College in 1850, and a member of the Georgia State and Spalding County Medical Societies, died at his home after a long illness, on March 17, aged 75 years.

Dr. CHARLES P. MARTIN of Jameson, Mo., a graduate of the University Medical College of Kansas City, in 1883, died at the Ensworth Hospital, St. Joseph, of peritonitis following an operation for appendicitis, on March 15, aged 50 years.

Dr. CHARLES BELL CONVERSE of Jersey City, N. J., a graduate of the Bellevue Hospital Medical College in 1871, a veteran of the Civil War, for thirty-six years county physician of Hudson County, and a member of the New Jersey State and Hudson County Medical Societies, died at his home on March 4, aged 60 years.

Dr. L. W. BROWN of Eugene, Ore., a graduate of the New York Homeopathic Medical College and Hospital in 1895, and a member of the Oregon State and Lane County Medical Societies, died suddenly of apoplexy on March 13.

Dr. MORRIS GUTH, medical superintendent of the Pennsylvania State Hospital for the Insane at Warren, Pa., died of heart disease on a street car in Erie, Pa., on March 27, at the age of 61 years. He was graduated from the medical department of the University of Pennsylvania in the class of 1870. He was a member of the Warren County Medical Society, the Medical Society of the State of Pennsylvania, and of the American Medical Association.

Dr. JOSHUA W. SEIBERLING of Hyneman-ville, Pa., a graduate of the Bellevue Hospital Medical College, New York, in 1873, died suddenly at his home, on March 23, aged 65 years.

Dr. THOMAS N. MCLEAN of Fergus Falls, Minn., a graduate of McGill University Medical Faculty, Montreal, in 1882, a member of the American Medical Association and of the Minnesota State and Otterfail County Medical Societies, and formerly mayor of Fergus Falls, died in Chicago on March 21, aged 53 years.

Dr. TAFOR R. WASHBURN of Donnellson, Iowa, a graduate of the College of Physicians and Surgeons of Keokuk, Iowa, in 1901, and a member of the American Medical Association and the Iowa State and Lee County Medical Societies, died at his home on March 21, aged 43 years.

Dr. WILLARD EDDY of Waterloo, Iowa, a graduate of the University of Michigan, Department of Medicine and Surgery, Ann Arbor, in 1803, died in a private sanatorium at Des Moines, on March 21, aged 78 years.

Dr. WILLIAM EDWARD HOLBROOK of Lynn, Mass., a graduate of the Harvard University Medical School in 1876, a member of the Massachusetts State and Essex County Medical Societies, and formerly city physician of Lynn, died at his home of acute indigestion, on March 23, aged 60 years.

Dr. CHARLES C. RAYBURN of Kewanee, Ill., a graduate of the University of Pennsylvania, Department of Medicine, in 1901, died of tuberculosis in Colorado Springs on March 20.

Dr. J. H. TIEDEMANN of Seattle, Wash., a graduate of the Long Island College Hospital, Brooklyn, N. Y., in 1894, died at his home on March 29, from hookworm disease, contracted, it is believed, while he was engaged in making tests for the same disease in San Francisco on soldiers returning from the Philippine Islands.

Dr. GEORGE RHOADS of Springfield, Mass., a graduate of the Hahnemann Medical College of Philadelphia in 1880, died at his home, on March 29, aged 53 years.

Dr. ANNIE M. TREMAINE of Fredonia, N. Y., a graduate of the Women's Medical College, New York, in 1899, died in the Willard Hospital, Willard, N. Y., on March 25, aged 47 years.

Dr. THOMAS J. BACKES of New York, a graduate of the Bellevue Hospital Medical College in 1895, died at his home on April 2, after a long illness.

Dr. AMOS GRAVES of San Antonio, Texas, a graduate of the Medical Department of the Tulane University of Louisiana in 1868, and a member of the Texas State and Bexar County Medical Societies, died at his home after a short illness on March 9, aged 70 years.

Dr. A. C. MCDOWELL of Lyndonville, Vermont, a graduate of the University of Vermont College of Medicine, Burlington, 1870, and a member of the Vermont State and Caledonia County Medical Societies, died at his home on March 2, aged 47 years.

Dr. N. E. METCALFE of Maplewood, Missouri, a graduate of the St. Louis University, School of Medicine, in 1902, died at his home on March 23.

Dr. WILLIAM E. HOAG of New York, a graduate of the New York University, Department of Medicine, in 1874, died at his home on April 2, aged 71 years.

Dr. WILLIAM T. MCNARY of San Jose, California, a graduate of the Hospital College of Medicine, Louisville, Kentucky, in 1889, died at his home on March 25, aged 64 years.

Dr. TIPTON A. GUNN of Lorraine, Virginia, a graduate of the Medical Department of the Tulane University of Louisiana, in 1900, died in the Virginia Hospital, Richmond, on March 3, aged 28 years.

Dr. GEORGE BANNERMANN MAXWELL, formerly of Attleboro, Vermont, a graduate of the Chicago Homeopathic Medical College in 1804, died at his home in Porters, Texas, on February 20, aged 52 years.

Dr. WILLIS M. WELLS of Fulton, New York, a graduate of the University of Vermont College of Medicine, Burlington, in 1874, and a member of the New York State and Oswego County Medical Societies, the Central New York Medical Association, and the Academy of Medicine, and physician to the Lee Memorial Hospital, died at his home on March 30, aged 61 years.

Dr. JAMES H. NOBLE of Eau Claire, Wisconsin, a graduate of the Hahnemann Medical College and Hospital of Chicago, a former Wisconsin State Senator, and a member of the Wisconsin State and Eau Claire County Medical Societies, died on March 1 at Roswell, New Mexico, aged 61 years.

Dr. DANIEL WINTER of Columbus, Kansas, a graduate of the Homeopathic Medical College of Missouri, St. Louis, in 1886, died at his home on March 24, aged 79 years.

Dr. CHARLES H. DAVENPORT of Fairburn, Georgia, a graduate of the University of Georgia,

Medical Department, Augusta, in 1891, an ex-mayor of his town and prominent in local affairs, died at his home on March 26, aged 46 years.

Dr. CHARLES S. SMITH of Campbell, New York, a graduate of the University of Buffalo, Medical Department, in 1890, died at his home of acute indigestion on March 29, aged 47 years.

Dr. GEORGE L. PLASLEE of Auburn, Maine, a graduate of the University of Vermont College of Medicine, Burlington, in 1883, died at his home after a short illness on March 31, aged 83 years.

Dr. DARIUS MASON of Spokane, Washington, a graduate of the College of Physicians and Surgeons, New York, in 1853, and a member of the American Medical Association and the Washington State and Spokane County Medical Societies, having served as president of the State Society in 1895, died suddenly of heart disease at his home on March 26, aged 82 years.

Correspondence.

THE PROPOSED INSANITATION OF THE CANAL ZONE.

To the Editor of the Medical Record:

SIR:—A recent telegram states that Colonel Goethals, chief engineer of the Panama Canal, advises that the jungles should be permitted to grow up in the Canal Zone after the completion and on the beginning use of the canal. The reason assigned for the permanence of this, to say the least, uncivilized condition, is that it would contribute greatly to the military defense of the canal. Without any expert knowledge upon this subject the writer is disposed to believe that the methods of modern warfare would soon overcome such fragile obstacles as the jungle might offer in opposing hostile invasion. The jungles, however, with all that belong to them, would create conditions so hostile to the maintenance of the health of the military force necessary to be quartered within the limits of the Canal Zone and of the official and laboring force which will be required to conduct the operations of the Canal that they would prove to be veritable "boomerangs," so to speak. The military force, the railroad and canal employees, with the officials, will constitute a permanent population of the Zone amounting to possibly 50,000, most of them brought there from climatic conditions very different from those indigenous to tropical regions. The climax of the great work of Colonel Gorgas in the maintenance of the health of those engaged in the construction work of the Canal would seem to be to make the Zone a great park—remove every vestige of the jungle, fill up or drain by sanitary methods the swamp areas, encourage healthful living by comfortable and sanitary house construction, destroy, so far as possible, every breeding and living place of the anopheles and stegomyia genera of mosquito by creating conditions hostile to their existence. Side by side with the military force, whose duty it will be to protect the Canal from hostile attacks, there must be a sanitary army composed of officers and men able and well equipped to wage persistent and vigilant warfare against the ever-present enemies—disease and pestilence. In this way would it seem possible to make the operation of the completed canal successful, as by such methods was its construction made possible.

J. EWING MEARS, M.D.

PHILADELPHIA, PA.

THE MODIFICATION OF COW'S MILK.

To the Editor of the Medical Record:

SIR:—Allow me to comment upon the formula given by M. A. Helfgott to modify cow's milk, and printed in the MEDICAL RECORD March 23, 1912. Dr. Helfgott desires to make a 20-ounce mixture to contain, as human milk does, proteids 1½ per cent., fat 4 per cent., and sugar 7 per cent.; and he recommends the following formula: Whole milk 7½ ounces, upper 4 ounces, of cream 2½ ounces, sugar 6½ drams, and water sufficient to make 20 ounces. By careful and accurate calculations we find the formula incorrect, as it gives an excess of proteids and a deficiency of sugar. The required percentage of proteids in 20 ounces is $20 \times 1\frac{1}{2} = 30$. What percentage of proteids do we get according to the formula? In 7½ ounces of whole milk we have $7\frac{1}{2} \times 4 = 30$; in 2½ ounces of cream, $2\frac{1}{2} \times 4 = 10$. Thus we get $30 + 10 = 40$ proteids, instead of 30 as required. In other words, we obtain $40 \div 20 = 2$ per cent. proteids—an excess of ½ per cent.

We will take now the carbohydrates. The required percentage in 20 ounces is $20 \times 7 = 140$. What do we get? $7\frac{1}{2} \times 4 = 30$; $2\frac{1}{2} \times 4 = 10$; 6½ drams sugar = 80. Thus we get a total of $30 + 10 + 80 = 120$. In other words the mixture contains $120 \div 20 = 6$ per cent. sugar, instead of 7 per cent. in human milk—a deficiency of 1 per cent. Let us take now Dr. Helfgott's own calculations. He begins with the proteids and says: "What percentage of proteids is required in 20 ounces? $20 \times 1\frac{1}{2} = 30$. How many ounces of whole milk will furnish it? $30 \div 4 = 7\frac{1}{2}$." Correct is the doctor so far. Further he says: "What is the percentage of fat required? $20 \times 4 = 80$. What percentage do we get from $7\frac{1}{2}$ ounces whole milk? $7\frac{1}{2} \times 4 = 30$. What percentage is missing? $80 - 30 = 50$. How many ounces of cream will supply it? $50 \div 20 = 2\frac{1}{2}$." Dr. Helfgott's fat computation is correct. The cream will supply the fat deficiency. But will it not supply also an additional 10 of proteids above that required to correspond to human milk?

In the carbohydrate calculation Dr. Helfgott made a mathematical error. He gives us the required percentage of sugar in 20 ounces correct, $20 \times 7 = 140$. But, computing the sugar missing, after taking 7½ ounces of whole milk, he says: Sugar supplied by the $7\frac{1}{2}$ ounces whole milk, $7\frac{1}{2} \times 4 = 30$; sugar missing $120 - 30 = 60$. And thus he wrongly figures the quantity of sugar to be added 6½ drams. Correctly, the figures are: Sugar required, $20 \times 7 = 140$; in $7\frac{1}{2}$ ounces whole milk, $7\frac{1}{2} \times 4 = 30$; missing sugar, $140 - 30 = 110$; sugar in $2\frac{1}{2}$ ounces cream, $2\frac{1}{2} \times 4 = 10$; still missing, $110 - 10 = 100$. An ounce of sugar is, therefore, to be added to make the required percentage. Of course, Dr. Helfgott may be right in ordering less sugar, as a child taking a mixture containing 4 per cent. fat and 2 per cent. proteids will probably get extra sugar in the form of starch. His calculations are, nevertheless, wrong.

Dr. Helfgott claims his formula to be easy to remember. By the physicians? No! It is much easier to remember Dr. Holt's formula: 12 ounces of 7 per cent. milk, or 12 ounces of the upper 16 ounces, than to remember $7\frac{1}{2}$ ounces whole milk and $2\frac{1}{2}$ ounces upper 4 ounces. Besides, a mixture containing 4 per cent. fat and 2 per cent. proteids does not suit every child, and we have

to resort to the formulas given in the text books to suit the condition and age of the child. As far as the mother is concerned, she will not remember anything. The physician must write out everything for her in plain letters and tell her to follow it closely while preparing the mixture. Dr. Helfgott's formula is also a disadvantage to the poor mother. She has to buy two bottles of milk, one for the whole milk and one to make the cream.

In conclusion I say Dr. Holt's formulæ are easy to remember and easy to calculate, and it is easy to vary the formula according to the need of the child, if the physician understands the fundamental principles—and every physician should understand the proper principle, logic and technique of the most important part in pediatrics, namely, the modification of cow's milk for healthy and sick infants.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

INSURANCE, CONFERENCE OF THE COLLEGES AND UNIVERSITIES—THE HOSPITAL OUTLOOK, FEARS OF ADMINISTRATORS—HYDRONEPHROSIS AND X-RAYS—RENAL CALCULI—KARL PEARSON ON HEREDITY—NASAL CASTS AND HEREDITY—OBITUARY.

London, March 22, 1912.

Yesterday the projected conference between representatives of the universities and the medical corporations anent the Insurance Act was held at the Royal College of Physicians and was fully attended. The meeting unanimously agreed that considering there is remarkable unanimity of opinion within the profession as to the attitude its members should adopt toward the working of the act "this conference desires to place on record its general approval of the principles which inspire that attitude, and while conscious that there is some difference of opinion with regard to details, expresses its willingness to support the demand that these principles should be recognized by those who are responsible for the administration of the act before medical practitioners consent to work under it."

The outlook for the hospitals under the Act continues to excite the gravest apprehensions among administrators. Yesterday Lord Rosebery at the Ventnor Consumption Hospital remarked that he did not pretend to be versed in the Act and he commented on the steady decline in the mortality from consumption. But with regard to the report he had to confess that the income for 1911 was £500 less than in the previous year, and part of that came from one gift of £1,000 which was put to capital. The death duties had no doubt, he said, told on the legacies, which in 1911 were only £597 in place of £2,042 in 1910.

At the annual meeting of the Brompton Hospital Lord Cheylesmore (president) had to lament an increase of the debt to £10,000 and said that unless substantial help was forthcoming they must either close some wards or limit the work of their sanatorium. He found Mr. Lloyd George had promised so much for sanatoria that many people thought these institutions would be state supported, but that was far from the case. Unless revenue increased they would have to ask patients who were insured under the Act to contribute toward the cost of treatment at the hospital.

The council of the Hospital Saturday Fund has issued a special notice to all collectors for it, "it cannot be too clearly or too emphatically stated that the beneficent work done by the fund is not by any means covered by the Insurance Act."

The diagnosis of hydronephrosis is seldom made until considerable progress has been made with the lesion. At the earliest stage there may be no symptoms to excite suspicion and even when functional disturbance is pronounced the signs of commencing dilatation are obscure and variable. Practically a diagnosis is rarely made or only a suspicion is excited until a tumor appears in the loin. This being so it is encouraging to hear that the *x*-rays are available in these cases. Dr. Thomson Walker read a paper at the Medical Society of London in which he said this method of diagnosis consists in (*a*) finding an increase in the shadow thrown by the kidney; to recognize early dilatation in this way special measurements in a fixed position must be most carefully made. (*b*) Pyelography, *i.e.* filling the pelvis of the kidney with an innocuous fluid opaque to the rays (as collargol) and obtaining a radiogram. The dilated pelvis he found less sensitive than the normal to distention.

Early dilatation was indicated by clubbing and elongation of the calices and the pelvis becoming globular. The angle of union of the ureter with the pelvis was shown and kinking could be demonstrated. The position of a calculus was shown by a shadow of the stone and so with other obstruction, *e.g.* kinking of the ureteropelvic junction or an actively contracting ureter due to movable kidney.

With regard to calculi in the ureter (apart from hydronephrosis) Mr. Thelwall Thomas gave to the Liverpool Institute on the 7th inst. a tabular analysis of seventeen cases on which he had operated and he said the most reliable sign was the presence of well-marked shadows on the radiogram in the line of the ureter, but even this was not absolute in the lower inch or so of the duct. In all cases pain had been present, in ten hematuria, in about half pyuria (in some of these with hematuria), in three there had been neither of these.

Professor Karl Pearson gave a lecture on the 12th inst. on "Tuberculosis in Relation to Heredity and Environment." To show how phthisis may attach itself to a family for from four to seven generations he exhibited three pedigrees on the screen. He said this might be from (*a*) an inherited constitutional factor; (*b*) an environment factor (house or occupation); (*c*) direct infection. But pedigrees demanded careful analysis. In two of those shown (German) 62 per cent. of the tuberculous members lived to adult age, 45 per cent. married, and only 12 per cent. who married into these stocks were tuberculous. In the third instance a generation had twice been skipped and the stock (landed gentry) had lived in three different countries and sought by change of climate and occupation to escape the family curse. Such facts must be carefully studied. We must consider whether persons running the same risks have the same liability. The professor said nature had done more than art in reducing the death rate of phthisis. Studying the fall it was found to be taking place in urban and rural districts, with and without sanatorium and dispensary treatment; it was begun long before the introduction of such treatment and it had not been accelerated by the increase of medical knowledge. It seemed, therefore, that they must regard the fall as part of the natural history of man rather than due to his attempts to better his environment. Perhaps the professor had in view only civilized man, for he remarked that the

race had risen through suffering both physically and mentally.

Dr. A. M. Gossage has reported to the Clinical Section of the R. S. M. that he lately came across a family several members of which had been troubled with a persistent fibrinous discharge from the nose. It was noticed at birth and continued throughout life, causing very little discomfort if the nostrils were kept clear but otherwise a bad smell, never ozena. Specimens from the father and two children were found to be complete casts of the nostrils. They reformed in about twelve hours. Films showed polymorphonuclear cells embedded in a network of fibrinous matter. There were bacilli, diplococci, and short diplococci, but neither *B. diphtheriæ* nor *B. xerosis*. Attempts to embed and cut sections failed as the material was too friable. At least four generations had suffered, males and females equally. The children of persons with normal mates were roughly half normal and half affected. There was no record of offspring from normal members of the family. It is certainly curious to find a fibrinous exudation on a mucous membrane resulting from some congenital abnormality and not from an infective inflammatory process.

Sir Richard Brayn, formerly medical superintendent of the Broadmoor Criminal Lunatic Asylum, died on the 12th inst., aged sixty-two. He qualified at the two royal colleges here in 1873-4 and entered the prison medical service in 1875. He served on the committee on inebriate reformatories and as a governor of several prisons. He received a knighthood at the coronation. As an expert his opinion was held of the highest importance.

Dr. G. C. H. Fulton, J.P., Medical Health Officer for Eston, died on the 9th inst., aged fifty-four. He qualified as Glasgow University, M.B., C.M., 1883. He contributed reports on vaccination, infantile mortality, etc.

The administrative medical officer of Bloemfontein, Col. F. J. Lambkin, R.A.M.C., died there on March 8, aged fifty-eight. He took the double qualification in Ireland in 1880 and joined the army medical service the next year. During the South African war he saw much service, taking part in the relief of Ladysmith, including the actions at Colenso, Spion Kop and Vaal Kranz. He also took part in the operations on the Tugela Heights and the action at Pieters Hill. He received the Queen's medal with five clasps and the King's with two. He was made lecturer on orphilology at the Army College.

Dr. I. S. Shillingford, who died lately after above fifty years practice in South London, had served in the army as surgeon before then. He was in the Crimean War and present at Alma, Sebastopol, and Inkerman. He served also in the Indian mutiny at Cawnpore and later at Delhi.

Dr. H. Banks, late medical officer of Oxford prison and of the Provident Dispensary and the Lying-in Charity Home, died on the 20th inst. in his seventy-seventh year. He qualified in 1858 and took M.D., St. And., 1859.

Results of Salvarsan in Obstetrics.—Jeannin states that in the case of the syphilitic mother the action of salvarsan is as good as that of mercury, the injection causing a rapid improvement of the symptoms. The drug has no bad effects on the fetus, development going on as if nothing had been done. Abortion or premature labor is not induced. In cases of congenital syphilis the effort to treat the child through the milk of the mother is futile. But intramuscular injections of salvarsan have an excellent effect on the child.—*La Presse Médicale.*

REPORT OF THE MEETING OF THE FAR EASTERN ASSOCIATION OF TROPICAL MEDICINE (*Continued*).

(From Our Manila Correspondent.)

HONGKONG, Jan. 27, 1912.

Fifth Day.

The first paper read was entitled "The Need for Physiological Standards in Clinical Research," by G. Duncan Whyte.

The next paper read was "The Care of Children in the Tropics," by G. Montagu Hartson.

The next paper was entitled "The Prophylaxis of Umbilical Tetanus at Saigon," by Dr. M. L. R. Montel. In this the author showed the desirability of making available for use sterile dressings with which to dress the umbilical stumps.

The next paper was entitled "Latest Researches Into Spotted Fever," by Dr. Fürth. In this paper the author gave a large series of blood examinations which had been made in connection with this disease, but without any tangible results.

The next paper was "Relapsing Fever and Its Treatment by Salvarsan," by Dr. W. V. M. Koch. This paper gave a series of cases in which salvarsan had been used with complete success in the treatment of this disease. After its administration no exacerbations of the fever occurred, and the remedy is undoubtedly the best that has yet been tried in this disease.

The next paper was entitled "Blood Pressure," by J. C. D. Allen. In this the author gave a résumé of the results which had been obtained by the use of the sphygmometer, and showed an instrument of special design which he had found satisfactory in his practice. In his opinion a continued residence in the tropics was responsible for an increase in the blood pressure. In the discussion which followed attention was invited to the experiments which had been made recently by Chamberlain and Vedder, in which, in a series of one thousand cases of periods of residence varying from a few months to ten years, the authors were of the opinion that the question of blood pressure depended largely on the manner in which the instrument was adjusted, and the personal equation, and, so far as their observations went, no distinct difference could be noted in individuals who had been but a short time in the tropics and those whose residence had been over a prolonged period of time.

Sixth Day.

The first paper was entitled "Malaria as a Factor in the Etiology of Biliary Calculi," by George A. Finlayson. In this paper the hypothesis was put forward that the malarial organism, or its product in the gall-bladder, served as a nucleus for biliary calculi.

The next paper, entitled "Remarkable Parasites in a Case of Tertian Malaria," by Captain H. M. Neeb. This paper was really additional evidence to support the contention which this author has heretofore made in connection with the parthenogenesis of the malarial parasites. The specimens which he exhibited undoubtedly showed the majority of the stages of the evolution of the parasite. The different forms could be clearly seen in the blood specimens which he exhibited to members of the Congress. The blood containing these parasites came from a young child. After the administration of quinine they promptly disappeared, thus eliminating kala-azar.

The next paper was entitled "A Demonstration of the Anopheline Mosquitos of India," by Major S. P. James. Major James brought with him a most complete collection of the various forms of the anopheline mosquitos and gave daily demonstrations of these at the bacteriological institute of the Department of Health at Hongkong.

The next paper, "Black Water Fever in Burmah," was by Lawrence G. Fink. This was read by title, and the next paper, "Mortality, Birth-rate, and Sanitation of Saigon," was also read by title.

The next paper, entitled "Town Planning and Sanitary Conveniences at Tsingtau," by Dr. Uthermann, was read by Dr. Fürth. In this the author showed a series of charts, tables, and maps, in which the sanitary improvements which had been made in Tsingtau since German occupation was graphically shown. The hygienic results showed to the best advantage among the German troops which were stationed there. A great reduction in venereal diseases among troops had been brought about by the prophylactic use of argyrol and calomel ointment. Water and sewer systems, garbage collection, and the other usual sanitary measures have also been carried out at Tsingtau with favorable results.

The next paper was entitled "Indian Native Coolie Immigration," by Sir Allan Perry. This paper was of considerable interest, in view of the success which has been had in Ceylon in preventing the introduction of dangerous communicable diseases, in spite of the close proximity of Ceylon to India and the large amount of communication there is between India and Ceylon owing to the coolie labor which is imported from India. The author invited discussion upon the best means of preventing the introduction of cholera. Dr. Heiser stated that the experience of the United States in connection with cholera which was brought to New York during the summer of 1911 would perhaps be of interest, in that the measures taken had proven completely successful, and had been much less annoying to commerce than those which had heretofore been employed. He stated that a rigid examination of stools of all steerage passengers had been made on vessels coming from ports in the Mediterranean, and that on the majority of vessels cholera carriers were found. These cases had been isolated until the disappearance of cholera vibrios from their stools, and in almost every instance it was possible to release steerage passengers who were negative after 36 hours of detention. The best test of the success of this method was probably shown by the fact that no introduction of this disease into the United States had occurred after these measures were adopted.

Dr. Sansom, of the Federated Malay States, stated that his experience had conclusively shown that in handling large numbers of coolies that were constantly coming into the Straits Settlements the ordinary quarantine period of five days against cholera was entirely inadequate; that numerous instances had occurred during the past year in which cases of cholera occurred eight days after the period of quarantine had begun, and he strongly urged that in cases where it was not possible to make microscopical examinations of stools the period of quarantine should be increased to ten days.

The next paper was entitled "The Necessity for Uniform Quarantine Regulations Among the Coast Ports of China," by Dr. Uthermann. The author invited discussion on the following points:

(1) The necessity for increasing the interchange of weekly news between the Northern and Southern ports.

(2) Ways and means to either obtain uniformity in the different Quarantine Regulations or to have the present regulations (especially as regards disinfection) acknowledged and agreed to. The necessity of this is shown by the following instance: During the outbreak of plague in the spring of 1911 steamers running from Dairen to Shanghai via Tsingtau had to be fumigated first in Dairen (by a special system of fumigation); two days later, on arrival at Tsingtau, again by means of the Giemsa Nocht apparatus, and once more on arrival in Shanghai (36 hours later) by means of the Clayton apparatus.

This led to the appointment of a Committee on Quarantine, the report of which will be given later.

Seventh Day.

The last day was taken up entirely with the business meeting, at which the resolution on beriberi, which had been passed on the second day, was modified and the following resolution was substituted: *Resolved:* That the accuracy of the opinion of this Association, recorded in 1910, has received further and more complete confirmation by investigators in Japan, China, French Indo-China, the Philippine Islands, Siam, Netherlands—India, the Straits Settlements, and the Federated Malay States, namely, that "Beriberi is associated with the continuous consumption of white (polished) rice as the staple article of diet." It is therefore again desired to bring this opinion to the notice of the various Governments concerned and to recommend international action.

After much discussion the following resolution upon quarantine was adopted: *Resolved:* That the resolutions adopted at the last conference be amended to read as follows:

1. To have a definition of the *Status Sporadicus* and a common standard for the term *Epidemic* when making reports to or imposing quarantine against each other. The following definitions were submitted for consideration: *Status Sporadicus,* in respect of any communicable disease, means the existence in a place within the next preceding fourteen days of a case or cases of that disease not definitely traceable to an imported case. *Status Epidemicus*: Plague, cholera, smallpox, yellow fever, typhus exanthematicus, trypanosomiasis, or other communicable diseases shall be considered to be epidemic in any port, place, or defined locality when after the first telegraphic report of the appearance or recrudescence of the disease any weekly report thereafter shall show the occurrence of an average daily number of three cases, exclusive of cases imported into or originating in a quarantine station.

2. To circulate weekly returns of plague, cholera, smallpox, yellow fever, typhus exanthematicus, and trypanosomiasis, and also of plague in rodents among the signatories; also telegraphic report on the first occurrence of any of these disease in a clean port or territory.

3. To issue a bill of health to all outgoing vessels proceeding to a port of another signatory. Such bill of health shall *inter alia* state the facts as to the existence and prevalence of quarantinable disease in the port, place, or defined locality, and further shall contain such other information as may be desired or deemed necessary by any signatory to enable such signatory to estimate the sanitary risk from

the arrival of the vessel in its (the signatory's) ports.

4. To report by telegram to the country concerned the departure of an infected or suspected ship (as defined by the Paris convention) which may intend to proceed to any port in the territories of another signatory; and to indorse the bill of health of the said infected or suspected ship with a full account of measures taken to disinfect or otherwise deal with the said vessel.

5. To meet point 22 raised by Dr. Othermann the following procedure is suggested: That in respect of any vessel leaving a plague-infected place or carrying persons or suspected cargo from such a place (a place where there is plague in man or rodents) it is considered that no subsequent disinfection or fumigation should be imposed on the vessel *at any port of call*, if it can be shown (*a*) that the vessel has been properly treated for the destruction of rats and other vermin, (*b*) that approved measures of inspection or examination and personal disinfection of effects have been carried out in respect of all persons on board such vessels, and (*c*) if specially objectionable classes of cargo (to be scheduled) have been rejected or properly disinfected before shipment. Provided further that it is understood that no evidence of plague is discovered on board in man or rodent at any port of call.

It was unanimously decided to accept the invitation of the French Government to hold the next meeting of the Congress at Saigon. Dr. Cleroq, Surgeon General of the French Colonial Medical Service, was elected *President*, Dr. Yersin was elected *Vice-President*, and Dr. M. L. R. Montel was elected *Associate Secretary* with Dr. Clark, who was again unanimously reelected for the position. Votes of thanks were passed and the other usual formalities carried out.

Members of the Congress were most kindly received by the residents of Hongkong, and all foreign delegates thereto were entertained in private houses of the residents of the colony. Theatricals, dinner parties, social functions, yacht trips, and other diversions were provided for the delegates in ample profusion, and all of them expressed their utmost gratitude for the hearty reception which they had been accorded and the facilities which had been extended them for acquainting themselves with the medical features to be observed in Hongkong.

The Masquerades of Chronic Cholelithiasis.—A. E. Austin states that in this condition the pain may be confined to the epigastrium and differ in no respect as far as location goes from the pain of gastric ulcer or nervous gastralgia. The jaundice, too, which is regarded as a cardinal symptom is often absent. On account of the ease with which a gastroptosis and a prolapsed right kidney can be found in women on account of their lax abdominal walls one is often apt to ascribe their attacks of pain in the upper abdomen to this cause; nothing could be more unjustifiable unless a careful investigation of the gall-bladder region is made. A prolapsed right kidney may not only simulate gallstone disease, and vice versa, but may actually be one of the exciting causes of such formation. A purulent gall-bladder may simulate a pyonephrosis.

Geographical Distribution of Insanity.—By E. E. Southard. (See "Eugenics and Geography," page 720.)

Suturing After Submucous Resection of the Nasal Septum.—O. A. Lothrop notes that many patients experience much discomfort for the first twenty-four hours after a submucous resection of the nasal septum. This is due in a large degree to the presence in the nares of splints, plugs, or packs commonly used to keep the flaps in approximation and to prevent the formation of a hematoma between them. Any foreign substance in the nose causes a local reaction and increases the nasal discharges. Such foreign substance also retains the secretions and favors the multiplication of bacteria. It was for the purpose of eliminating this discomfort to the patient after operation and to dispense with any packing whatsoever that the following procedure of suturing the flaps together was devised: The technique of suturing, after the resection has been finished, consists in passing a stitch preferably of plain catgut, No. 0, from one side of the nose completely through both septal flaps into the other side and fastening it so that the flaps are held tightly together at that point. Several points should be thus fixed throughout the resected area, so that the septum is given a quilted appearance. The ends of the suture thus passed through both septal flaps may be tied loosely over the columella. This method not only fixes the point of passage through the flaps, but causes the sutures to lie against the mucous membrane on either side like guy ropes. Thus, these sutures have a fan-shaped appearance, being tied at one point over the columella and spreading out to divergent points on the septum. The columella should be protected by tying the sutures not too tightly over a bit of cotton or other protective.

Safety Valve in Intratracheal Anesthesia.—F. J. Cotton and W. M. Boothby allude to the dangers of emphysema and of interference with the circulation (prevention of filling of the right heart) by excessive intrapulmonary pressure; the physiological literature gives ample evidence of all kinds that a pressure in excess of 10 mm. Hg. is unjustifiably dangerous. To prevent this danger Boothby, working with Ehrenfried, adopted the simple expedient of a mercury safety valve. The simplest form is a bottle containing mercury; in the cork are two holes—one for the passage of a glass tube connected with the air current near the mouth of the patient, which dips into the mercury a distance of 10 millimeters; the other hole is for the escape of the air from the bottle, which (to prevent the loss of mercury) can be filled with a short glass tube plugged with cotton. Any increase in pressure above 10 millimeters anywhere in the apparatus will escape by bubbling through the mercury. The tubing to the safety valve must be of as large caliber as that of the rest of the system so as to take care of any volume of air that the apparatus might suddenly deliver.

Detection of Bile in Stomach Contents.—H. W. Goodall states that the following method, which is based upon the oxidation of bilirubin with nitric acid, forming green biliverdin, is recommended as being delicate and easy of application. Half a test-tube of the fluid portion of the stomach contents is taken. If this amount cannot be obtained, or if the contents consist largely of solid material, they should be diluted with water, thoroughly mixed, and the fluid portion poured off or filtered. The fluid is then saturated by shaking one or two minutes with ammonium sulphate crystals, or, better, crystals which have been ground into a fine powder. About an inch in the bottom of the test-tube is usually sufficient. Then from 1 to 3 cubic centimeters of acetone (about a quarter of an

inch in the test-tube) are added, and the whole t[illegible] mixed by inverting the test-tube five or six tim[illegible] best not to shake the test-tube. After standing a [illegible] two the acetone rises to the surface of the fluid [illegible] bile pigment up with it. A drop of yellow nit[illegible] allowed to run down the side of the test tube [illegible] green reaction occurs in the acetone layer. Care [illegible] taken in adding the acid, as too large quantities [illegible] too rapid an oxidation and the green quickly pass[illegible] into a purple or reddish color. If the acetone does not promptly rise to the surface the liquid has not been thoroughly saturated with ammonium sulphate. If too much acetone is added the bile may be diluted to such a degree that the reaction is not distinct. This procedure is delicate enough to demonstrate bile in contents which macroscopically do not suggest its presence.

Chemotherapy of Cancer.—W. J. Morton refers to the fact that he first drew attention nine years ago to the utility of the aniline dyes, particularly the fluorescent kind, in the treatment of cancer. The method he pursued was to saturate the patient, including his cancer tissue, with the dye, which, was administered by the mouth, and then to subject the cancer to the action of the beta ray either of the *x*-rays or of radium. In some cases his results were apparently favorable. He suggests that it might be possible to administer to the patient by the mouth separate drugs at separate times, counting upon their curative reaction within the cancer cell itself by chemical combination made within the body instead of outside of it. The cancer cell would correspond to the laboratory test tube.

Recent Views on Endometritis.—R. T. Frank notes that anatomical evidence of inflammation is demonstrable in less than half of all cases of endometritis. Many cases which anatomically show the presence of inflammation give no corresponding clinical symptoms. A majority of cases which show the conventional symptoms of endometritis (leucorrhea or bleeding) are wanting in demonstrable anatomical signs of inflammation. Therefore, in most cases one is obliged to search for other etiological factors to account for the symptom-complex hitherto called "chronic endometritis," and to devise for it a more logical treatment than curettage, intrauterine applications, or vaginal douches.

Ionic Surgery in Cancer of the Rectum.—G. Betton Massey, on the basis of seven successful results in fifteen unselected, or but partly selected, cases of carcinoma and sarcoma of the rectum and anus, extols the value of cataphoresis, or ionic surgery, in selected cases of these affections. The chief indications for the use of the method are found in cases involving the sphincter, conditions that interfere with successful eradication by excision, and in growths of the middle and upper rectum. In these it is possible to eradicate the disease without injury to the sphincter. The simplicity of this method in an inefficient case, with its bloodlessness and the short period of anesthesia required, should stimulate physicians to treat at once their so-called hemorrhoidal patients at once; in this may be done with great thoroughness by the [illegible]led finger. Should the examining finger detect an [illegible]nted internal pile, or an ulceration with indurated [illegible] the case should be regarded with suspicion at once. The growth may be syphilitic in rare instances and further investigation may be needed, but immediate destruction or removal will do no harm and may save the patient's life.

The Dispensary Evil and the Social Worker.—S. H. Brown states that the very poor who apply to the dispensary for treatment are not possessed of the happy faculty of evoking the kindly and courtly consideration that is due human beings, and they are likely to be hurriedly dismissed with a prescription of doubtful value in order to be disposed of as soon as possible. If their case or cases present features of unusual character, on the other hand, attention is carried to the other extreme and the treatment becomes more of a burden than the disease. Trivial affections in the very poor are of greater importance than the same class of ailments in the less unfortunate class of people because they are attended with grave fears and premonitions. Very frequently such patients are incapacitated for work by conditions that appear to the dispensary physician of no gravity; he dismisses the patient with more or less vague and often gruff explanations of the condition. Not so, however, with the better dressed and perhaps more polite, and doubtless better paid, dispensary patient. To the latter, the dispensary physician is frequently all courtesy notwithstanding that this particular individual represents the class that is doing most harm to the medical profession, and in himself constitutes the entire dispensary evil. The social worker can readily determine the home life, habits, salary, etc., of dispensary applicants, and after repeated visits, in most instances, the individual who is imposing upon the charity of the dispensary will voluntarily refrain from continuing to draw upon the dispensary for relief.

Sanitation in Panama.—W. C. Gorgas describes the conditions at Panama and gives the history of former conditions when the Isthmus was considered the most unhealthy spot in the world. During the construction of the Panama railroad the mortality was so great that the construction work had to be stopped several times. At one time the construction company imported 1,000 negroes from Africa, who all died within six months, and the same fate occurred to 1,000 Chinamen. The mortality rate was similar during the French work on the Isthmus, and the author estimates that they lost 40,000 laborers by death during that period. The mortality at the present time is 7.50. Malaria, from a maximum of 821 per 1,000, has been reduced to 187 per 1,000 morbidity; but, best of all, yellow fever has been completely banished. The general death-rate has been reduced during six years from a maximum of 40.04 per 1,000 to a rate for the year of 1910 of 2.18 per 1,000, which compares favorably with many parts of the United States. What the author particularly emphasizes, however, is that, while the great work done of late

years in tropical sanitation has enabled the sanitary department on the Isthmus to take a vital part in the building of the canal, this is not the greatest good that is hoped and expected will flow from this conspicuous object lesson. He hopes that our success at Panama will induce other tropical countries to adopt the same measures and thereby redeem the tropics and make them a suitable habitation for the white man.

Value of Psychology in Psychiatry.—A. Meyer states that psychology will become a much more real issue when it aims to guide students in the correct and critical recording of the plain facts of conduct and behavior and the mechanisms at work; when it puts the emphasis on what shows objectively as well as subjectively, namely, the conditions, types and results of mental activity; when it trains the student to see, in the special psychological methods, methods of accuracy and greater comparability; but above all, when the data can be formulated in terms of adaptations of a living functioning organism with the system of mental integrations, the conditions and structure of which are becoming increasingly better understood. The student should learn that psychology is the study of a certain type of reactions, of the conditions under which they occur, of what they do and how they can be modified and kept from miscarriage. How to use the reactions either as mere signs of broader disorders or as dynamic factors must be learned in the study of cases and by experimentation.

Trachoma.—I. W. Crigler states that trachoma is a disease of the conjunctiva in which there is a characteristic connective-tissue hyperplasia and a proliferation of lymphoid cells. The follicles formed by this proliferation tend to degenerate and become encapsulated by the new connective tissue. They become distended with fluid, push their way to the surface of the conjunctiva, degenerate and break down, and the conjunctiva is replaced by scar tissue. As a result of the chronic inflammatory process other changes take place leading to a general atrophy of the lid. The author emphasizes the fact that the disease is a chronic one, the acute malignant cases being the exception, and notes that it is greatly to be deplored that there is no diagnostic character to distinguish it to the general practitioner from chronic follicular conjunctivitis. One is compelled to wait until the second or hypertrophic stage before one can make a sure diagnosis and this is often only after months. Follicular conjunctivitis tends to spontaneous recovery, leaving a normal conjunctiva. Trachoma never does. The medical treatment has not advanced during the past decade, but it cannot be said that the remedies are without effect. The treatment with nitrate of silver and copper sulphate is painful and the patient discontinues them as soon as a little relief is obtained. Relapses then occur and the disease progresses. While a good many cases of true trachoma have been arrested, the author thinks a too large number are so credited and that all cases that respond to expression should never be called trachoma though they present the picture of this disease for a time. He speaks of the importance of the surgical treatment, which he considers the most successful means of combating the condition.

Cutaneous Reaction in Gonorrhea.—E. E. Irons notes that in recent experiments with glycerine extracts of the gonococcus he has found that a well-defined cutaneous reaction, similar to the cutaneous tuberculin reaction, occurs in cases of gonococcal infection, when the extract is introduced into the skin by the method of von Pirquet. In positive cases in from twelve to twenty-four hours, an area of hyperemia from 5 to 10 millimeters in diameter appears around the point of inoculation of the extract. Frequently a definite papule develops. The control inoculation, using a similarly prepared glycerine extract of the washings from the same number of uninoculated culture tubes, shows only the point of needle puncture. In normal persons, and in those suffering from non-gonococcal infections, the inoculation of the gonococcal extract produces no more reaction than the control inoculation, or at most a small area of redness 2 to 3 millimeters in diameter.

Cystoscopy in Surgical Diseases of the Kidney.—F. W. Griffith states that in cystoscopy there is a means of exact diagnosis which is not sufficiently utilized. There is no other renal disease in which the cystoscope is more useful than in renal tuberculosis provided the case is seen early. It is as necessary for the detection of an early lesion as is the stethoscope in early pulmonary tuberculosis. In nephroptosis the use of the cystoscope is chiefly in diagnosis and in the selection of cases for nephrorrhaphy. This condition occurs in about 20 per cent. of all gynecological cases. In nephrolithiasis the cystoscope is of especial value in corroborating the findings of the *x*-ray, in determining the presence of infection, and in estimating the absolute and relative ability of the two kidneys. As a rule it is neither difficult nor dangerous to catheterize a kidney and if made a routine practice this procedure will lessen the number of mistakes. There are many other conditions, such as pyogenic infections, malignant growths, and cystic kidneys, in which the use of the cystoscope is almost indispensable for diagnosis.

The Lancet.

March 23, 1912.

Paratyphoid Fever.—F. A. Bainbridge states that there is no real distinction between the disease caused by *Bacillus paratyphosus A*, and that caused by *Bacillus paratyphosus B*. The clinical symptoms and post-mortem appearances are practically identical; and in both cases the disease appears to be spread mainly, if not entirely, by human carriers. Both organisms usually give rise to an illness clinically resembling typhoid fever, although very ocasionally they set up acute gastroenteritis. The only important points of difference between infection by both paratyphoid organisms consists in the varying response of the patient as regards the production of agglutinins in his serum. Up to the present most of the carriers of the paratyphoid A bacillus which have been recognized have been of the acute variety, whereas the carriers of *Bacillus paratyphosus B* are chronic carriers. This apparent difference probably depends upon the special circumstances under which paratyphoid A fever in India has been studied.

Feeble-Mindedness and the Binet Method.—W. C. Sullivan refers to one of the limitations which is implied in the very description of the Binet method as furnishing a measure of the intelligence. It is designed *only* as a measure of the intelligence; it does not purport to enlighten one as to the affectivity or the will. In regard of feeble-mindedness, at all events as the question concerns the community, as notably with reference to the feeble-minded criminal, it is these latter factors of mind that are of most importance. Therefore the method is to that extent an instrument of limited value in the examination of the mentally defective. On the other hand, even in such cases, it is of no small assistance to be able to separate, as it were, this one factor of the intelligence, to measure it and to assign to its deficiency the due share in the individual's

inferiority. And, moreover as the factors of mind [illegible] after all intimately connected, many of the tests specially directed to the intelligence necessarily give one also some indirect indications touching emotivity and impulse.

Pharyngeal Suppuration.—G. W. Badgerow states that pharyngeal suppuration, according to its seat of origin, may be: (1) lymphoid; (2) submucous; (3) subaponeurotic; (4) prevertebral. Although suppuration arising in the lymphoid tissue of the pharynx is by far the commonest seat of infection, it is seldom that we find any large collections of pus in this layer of the pharyngeal substance. In acute lacunar tonsillitis the crypts may contain pus which either confines itself to the separate lacunæ or spreads as a false membrane over the tonsillar surface. Suppuration originating in the submucous tissue of the pharynx is the form which most often presents itself to the surgeon, and is best exemplified by peritonsillar abscess. The most prominent symptom in all submucous affections is dysphagia. This is due partly to the presence of the swelling, but mostly to the pain caused by pressure on delicate nerve endings. Trismus is also largely reflex in order to prevent pain. To suppuration occurring in the space between the pharyngeal aponeurosis and the prevertebral fascia some writers would confine the term retropharyngeal abscess. The term subaponeurotic suppuration would include not only an abscess originating in the deep cervical glands and presenting at the back of the pharynx, but also the particular form of submaxillary phlegmon known as angina Ludovici, while it would exclude an abscess the origin of which was due to caries of the cervical vertebræ or caseation in the postpharyngeal gland. Prevertebral suppuration is that with which the name of retropharyngeal abscess is almost always associated in the mind of the genefal practitioner.

Acute Myelitis with Optic Neuritis.—E. F. Clowes reports the history of a case characterized by an acute ascending paralysis, commencing with indications of meningitis in the form of acute pain and spinal rigidity. Vision was impaired on the following day, and on the day after this evidence of slight papillitis, more on the right side, was observed. The upper limit of hyperesthesia was one inch below the nipples. On the ninth day of illness the breathing was almost entirely abdominal, but the arms could be moved apparently without any loss of power. On the fourteenth day marked dysphagia set in, and the patient died while attempting to swallow fluid.

Dietetic Treatment of Diabetes.—P. J. Cammidge states that when working out a diet for a diabetic it is important to bear in mind that he must be supplied with approximately 34 or 35 calories per kilogram of his body weight, and that these must be contained in materials which experiment shows he can utilize. It is therefore necessary to ascertain, first, how much, and what kinds, of carbohydrate can be used with safety to supply the needful energy; secondly, what amount of protein is required to maintain nitrogenous equilibrium; and, thirdly, how much fat must be added to the diet to make up the balance of energy required. The amount of carbohydrate that can be safely allowed is worked out by adding known quantities of various carbohydrates to a carbohydrate-free diet and watching the effect on the urine. If the patient has a low coefficient of excretion, the output of ammonia is not high, and nitrogenous equilibrium is well maintained—that is to say, if it is a mild case—he should be put upon a diet containing about 3 ounces of bread, which corresponds to about 47 grams of added carbohydrate. If the urine is found to be free from sugar upon this, the daily amount of bread is gradually increased until glycosuria reappears. If, on the other hand, 3 ounces of bread are sufficient to cause sugar to appear in the urine, the amount is gradually reduced until either the glycosuria ceases or a carbohydrate-free diet is reached. In the former case, as in the first instance, the limit of tolerance for bread is that amount which just falls short of producing glycosuria. In any case it is generally advisable to place the patient on a diet containing no added carbohydrate for a week or two, when his tolerance is again tested. In most cases it will be found to have increased, and may in some instances approach the normal. It is now tested for other forms of carbohydrate by adding weighed quantities of these to the "carbohydrate-free" diet on separate days. Finally, a mixed diet containing a little less carbohydrate than has been found to be the toleration limit, and calculated to yield the requisite number of calories, is worked out from these data.

Immediate Results of Sanatorium Treatment.—J. A. D. Radcliffe states that with sanatorium treatment alone one can only reckon on 20 to 25 per cent. of all cases losing their bacilli as an immediate result of the treatment. When a combination of tuberculin with sanatorium treatment is adopted, at least 50 per cent. of the cases will lose their tubercle bacilli. The earlier the cases come under treatment the better the results. This is very strikingly shown in the tables in which the cases are considered in groups according to the stage of the disease. A comparison of the immediate results is so much in favor of tuberculin that it is difficult to understand the opposition to its employment, both in treatment and diagnosis

Vaccine Therapy in Diseases of the Eye.—C. W. G. Bryan states that in recent years the two most important methods of dosage which have been employed in using tuberculin in eye disease are: (1) Wright's method, commencing with a small dose, 1/80000 to 1/10000 milligram, gradually increasing the dose over a long period of treatment with about ten days' interval between each inoculation, the dosage being regulated by estimations of the opsonic index, and (2) von Hippel's method of treatment with tuberculin T.R., commencing with an initial dose of 1/500 milligram, repeating the inoculation on alternate days, increasing each time by 1/500 milligram until 1/50 milligram is reached; after this the dose is increased each time by 1/50 milligram up to 1/5 milligram; then by 1/10 milligram until a dose of 1 milligram is reached. During the treatment the temperature should not rise above 100° F.; if it does so, the previous dose, or a smaller one, is repeated until there is no rise of temperature after the inoculation. The author has used Wright's method, regulating the treatment partly by estimation of the opsonic index, partly by observation of clinical signs and symptoms, temperature, amount of pain and photophobia, effect on vision, and conjunctival injection. The results in the treatment of tuberculous conjunctivitis are good, provided the treatment is persisted in over a long period. The author has treated one case of tuberculous interstitial keratitis with excellent result. Others have reported favorable results in the treatment of scleritis, sclerokeratitis, and phlyctenular ophthalmia. In internal tuberculosis of the eye the results of treatment by vaccine are good, especially where the iris is the diseased tissue. The iris is favorable for treatment because it has a good blood supply. In tuberculosis of the fundus, where the supply is poor, treatment has to be prolonged and is less successful.

Some Intracranial Conditions.—S. Lodge reports a case of extradural abscess over both frontal lobes, resulting from traumatism. There was a Pott's puffy tumor over the right frontal region. Operation relieved the cerebral symptoms, but death resulted from chest complications. There is also reported a case of tic douloureux completely cured by extirpation of the sensory root of the Gasserian ganglion. The third case reported is that of congenital hydrocephalus in which recovery followed the drainage of both lateral ventricles. Another case was that of internal hydrocephalus simulating tumor of the right occipital lobe, cured by drainage of the lateral ventricle. In addition to other cases, the author reports five cases of hyperpituitarism. From the latter he concludes that partial hypophysectomy is indicated in all acute cases of acromegaly. The number of successful operations is now considerable, and acromegaly is rarely, some authorities say never, caused by malignant growths. In chronic cases of acromegaly, with considerable remissions and an absence of eye changes, the patients should be encouraged with the hope of a possible cessation of the disease; symptomatic treatment should be adopted; and, should eye changes occur in the chronic form, Cushing's internuscolotemporal method of decompression is indicated to avert the onset of blindness.

Spinal Analgesia.—A. E. Barker records the results of his experience with this method in 2,354 cases. The injection fluid consists of stovaine 5 parts, glucose 5 parts, and distilled water 90 parts, all by weight. It is as nearly as possible isotonic with the blood, and has a specific gravity of 1,023, as against that of the cerebrospinal fluid, which is 1,007. Injected slowly through the hollow cannula into the dural sac it remains, being heavy and slightly viscid, to a large extent unmixed with the cerebrospinal fluid, and seeks in a thin stream the lowest level it can find, where it pools and continues for a long time undiffused, as proved by experiment. The average dose of stovaine was 5 centigrams—that is, 1 cubic centimeter of the 5 per cent. solution. Very rarely was this raised to 6 centigrams; often it was reduced to 4 or even 3. Except for perineal and rectal cases, the lateral position was the rule, and great care was taken in regulating the curve of the spine, with the head raised on a small hard bolster made for the purpose of a definite height. In introducing the hollow needle the aim of the operator should be in every case to strike the dural sac exactly in the middle line. Moreover, the needle in entering the sac should always have its opening turned toward the patient's head.

Boracic Acid Poisoning.—J. H. Sanders reports a case of this condition resulting from the use of rectal irrigations of boracic acid solution in the treatment of dysentery. The symptoms were a rash resembling a bromide rash, delirium, and feeble pulse. This case illustrates the sudden onset of symptoms without any warning. It shows also the long duration of the rash after all drugs had been stopped, the delirium that accompanied the poisoning, the weakness of the pulse and danger to life if they are not recognized at once and stopped. The case shows also the possibility of mistaking the hard shotty papules for variola in its later stage, and also shows the inadvisability of any one out of reach of skilled medical advice using boric acid rectal injections for dysentery.

Deutsche medizinische Wochenschrift.

March 14, 1912.

Anaphylaxis and Internal Secretion.—Schittenhelm considers the relationship of these phenomena to proteid catabolism. In bacteria from without we see the source of a heterologous albumin, otherwise a toxalbumin, which produces the anaphylactic shock or reaction, etc. The question next comes up, are there circumstances in which the individual's own catabolic products are able to cause anaphylactic phenomena? A whole series of clinical phenomena may depend upon such a possibility. At present we think first in this connection of puerperal eclampsia, which possesses analogies with anaphylactic shock, yet seems to be due to homologous albumin, unless, indeed, it is somehow dependent on diet albumin, and this to some extent appears to be the case. It does not appear that unchanged albumin is at fault whatever its source; but with the first cleavage products, whether from heterologous or homologous albumin, we are dealing with toxic material. Peptones of any origin set up a characteristic syndrome of intoxication which closely resembles the anaphylactic reaction. Typical of the latter is spasm of the bronchi, and this may be induced at will in guinea pigs by merely injecting peptones. The bacterial toxins have usually been spoken of as albumoses, but before we can set down anaphylaxis straightway to albumoses or peptones it will be necessary to test all products of proteid decomposition in this respect. This has been summed up in the past under the familiar term ptomaine poisoning, and the syndromes caused by peptones and ptomaines have been largely the same. According to the author, the diamines, which are equivalent to ptomaines, cause no more nor less than peptone poisoning. Naturally the constitutional effects in so-called ptomaine poisoning must not be confounded with the irritant local effects of eating decomposed food, the latter representing the local shock, which is comparable with the local reaction in cholera, dysentery, typhoid, paratyphoid, etc. Under normal conditions toxic decomposition products are detoxicated largely by pairing; while an anaphylactic shock represents not one reaction, but a summation of many reactions, each due to some unsatisfied clearage product. Naturally an individual is seldom poisoned by his own catabolic products, but when this occurs the symptoms should not vary essentially from those due to heterologous albumin. In regard to hormones or internal secretions which are produced in certain organs and induce physiological and under certain conditions pathological changes in other organs these should consist of catabolic products of tissue albumin, and chemically these substances should be closely allied to soluble clearage products. While secretin has not yet been isolated, a substance with similar physiological action has been obtained in betaimidazolylethylamin from the ox's small intestine. In composition and action such substances resemble the active principle of ergot. In other words, analogies are at once apparent between the composition and activities of three great classes of substances: certain poisonous diamines or ptomaines, certain so-called internal secretions, and drugs having an arsenic component.

Inheritance of Disease.—Pick continues his studies along the line of Mendelian inheritance of disease and has aroused much interest among numerous colleagues. On the one hand, Mendelism must be studied from the viewpoint of familial diseases, the number of which is constantly increasing. Since many newly described diseases have a strongly familial incidence one might at first sight suppose that new types of disease originate in this manner. From quite another point of view we should study the incidence of disease in the progeny of known blood relatives, as well as in that of a mixture of races. A third study is double or bilateral heredity, which naturally stands in close relationship with consanguinity. The subject of equivalents complicates this study since a metabolic disease may be manifested in a number of different ways, as may also a psychoneurosis. In order to obtain data as to recessive qualities a very large material is necessary including not only three or four generations, but many individuals in the later ones. Even in tracing dominant characters many obstacles are encountered, such as a small number of offspring and the sex element. Once Mendelism can be proved in a stock which is suitable for analysis, its presence can be predicated in other stocks.

Insurance Medicine.

LIFE INSURANCE AND THE CONSERVATION OF HUMAN LIFE.*

By J. S. LANKFORD, M.D.,

SAN ANTONIO, TEX.

MEDICAL DIRECTOR SAN ANTONIO LIFE INSURANCE COMPANY.

Life insurance companies have been looking backward for three or four decades and insuring lives upon the estimates based upon the classified experience tables. These actuarial investigations and reports have been an invaluable aid in selection and great saving in mortality. Actuarial study should not only be continued, but prosecuted with increased vigor and intelligence. We should face about, however, and look to the future.

It seems strange indeed that life insurance companies with so much brains involved in their management, have so long overlooked the immense possibilities of prolonging the lives of policy holders and increasing dividends by attention to the conservation of human life. Stockholders want dividends and policy holders desire long life. Why not add to longevity and accomplish both? It can be done by proper control of sanitary conditions and by teaching policy holders how to live.

Scattered efforts have been made recently by some progressive companies, but there should be universal and united effort. This is preeminently a day of organization and a strenuous endeavor should be made to interest all sound and progressive companies until there is a general movement, and then all such work should be assembled and directed by a *life insurance board for the prevention of disease* to be established in Washington in close friendly relationship with the government departments, but in no way connected with the government. Such a board could be manned by great leaders in science, engineers, sanitarians, and competent clerical forces with proper equipment that would accomplish some marvelous results.

The duties of such a board would be deep scientific research in biology, pathology, and the cause of disease; careful study of the most scientific disposal of sewage and pure water supply in abundance; investigation of local epidemics by experts, and close cooperative efforts with constituted health authorities for relief; educating the public in sanitary matters by stereopticon lectures, reaching especially our twenty million impressible school children; cooperation will all organizations for the benefit of public health, and especially by teaching the policy holders of interested companies the laws of longevity by a well edited monthly publication.

One very easy and powerful method of education would be to keep several pleasing lecturers in stereopticon lecture work in schools, showing how typhoid fever, malaria, tuberculosis, hook-worm, and other infectious diseases may be prevented. These lectures are interesting and there is no difficulty in gaining access to the schools. Such valuable men as Hiram Messenger could be kept on the road investigating local conditions that affect human life and encouraging improvement. The field of usefulness of such an organized force would be continually revealing new possibilities. A plan could be easily worked out for an efficient force and proper equipment, and a limited amount per year, subscribed pro rata by interested companies according to their size, would bring back enormous returns in a few years in the saving of mortality.

It seems to me that the American Life Convention with its well known economy and progressive policy should be interested in such a proposition. Life insurance companies would become public benefactors, save much suffering, and add to the sum of human life and happiness, while operating in their own selfish interests.

For many years I have been interested in the prevention of disease for humanitarian reasons, but I have been impelled to present these thoughts in the interest of insurance after a personal investigation of the marvelous sanitary work done by Gorgas in the Canal Zone. Colon has a population of 10,000, but those in the city of the dead number 167,000. All of that part of the isthmus was formerly a seething mass of rottenness and death was undisputed king. Now this unhealthiest of all countries, under most adverse climatic conditions, has been made the healthiest known part of the world, with a death rate of less than four per thousand among white employees and at a cost of one cent per day a man for the prevention of disease.

This will indicate in a relative way what insurance companies might accomplish in promoting the longevity of policy holders by well directed efforts.

*Read at the midwinter meeting of the Medical Section of the American Life Convention, held in San Antonio, Texas, February 28-March 1, 1912.

French Statistics of Accidents to Workmen for the Year 1911.—In the *Journal Official* the following statistics regarding accidents in the various professions are given and may be of use for rating on hazardous occupations in life insurance: The total number of accidents registered was 6,463; 513 were fatal accidents, and of the others 24 per cent. produced permanent incapacity for work, and 5.91 per cent. caused partial permanent incapacity. The fatal accidents occurred in the following occupations: 67 deaths amongst miners and salt mine workers; 19 deaths in stone pits and quarries; 16 among employees in chemical manufactories; 28 deaths among metal workers; 101 in builders; 46 deaths from street accidents, etc.; 74 deaths among railway employees; 12 deaths in those employed in shipping and harbor work.

Operations on the Ear in Relation to Life Insurance.—F. Röpke notes that a great many expressions of opinion have been registered in regard to the important problem as to whether individuals who have undergone the radical operation should be recommended as acceptable risks. All observers are unanimous that no such applicant should be accepted until the primary ailment, namely, the aural suppuration, has been cured. Politzer is even opposed to the acceptance of cases that have been cured by means of the radical operation, on account of the danger of recurrences. On this point Bruhl points out that recurrence may take place many years after a case has healed. Further experience is necessary before the question can be decided whether cases radically operated upon can be accepted, at any rate, two years after the operation. Lermoyez and Boulay maintain that true bony recurrences are extremely rare. Most of the instances are cutaneous recurrences, which as a rule are quite harmless. These authors favor acceptance of the risk, provided the case has not been one of tuberculosis or of cholesteatoma. In the latter two instances they would require a postponement for two or three years after complete cure has resulted. Burger favors the acceptance of applicants who have submitted to the radical operation, but only at an increased premium. On the other hand, Marcioli and

Grunert favor an unconditional acceptance if complete cure has taken place. Zemann and Levy note that the various companies, according to their experience, take a varying attitude with reference to this subject. Zemann alludes to two cases that were rejected by one company but were accepted by another without increased premium.

In order to get more light on this subject the author addressed himself to Professor Florschutz, the medical director of the Gotha Life Insurance Company. The latter stated that just as carefully as the company regarded every case of aural suppuration and demanded that this should be definitely arrested, just as greatly, on the other hand, did it value the treatment by the otologist. Without further question, and at a normal premium, the company accepted an applicant who presented the aurist's certificate that suppuration had been arrested and that there was no prospect of future danger. This attitude was the same for all cases that had submitted to the radical operation, whether this was for an acute or for a chronic otitis media. The question now presents itself: What cases are to be regarded as cured? The author answers this by stating that cure has taken place in all cases in which smooth epidermization of the bony canal has occurred. The author does not hesitate to characterize those cases as cured from the life insurance viewpoint, in which, with an otherwise smoothly covered cavity, epidermization of the tubal orifice has not taken place. The accumulations of mucus starting from the Eustachian tube are easily set up, but have no significance so far as the outlook of life is concerned, principally because in the case of applicants for life insurance one has to deal almost exclusively with individuals belonging to the better classes, who would naturally be expected to keep the ear from becoming completely stopped up with the discharge. Naturally, a prerequisite to acceptance in these cases is that the individual is otherwise in good physical condition.

If at the radical operation it was necessary, on account of labyrinthine suppuration or intracranial complication, to enter the labyrinth or cranial cavity, this circumstance should not weigh against the acceptance of the risk, provided that the applicant has been completely cured, both subjectively and objectively. However, in this case, repeated and careful examination is necessary, particularly if one has not treated the individual before. It is also necessary to bear in mind that the applicant might minimize or even deny any subjective difficulties in order to be accepted. In borderland cases the companies protect themselves by granting short-term insurance or demanding an increased premium. In the case of simple operations on the ear, such as paracentesis of the drum membrane, the removal of polyps, and extraction of malleus or umbo, which operations are undertaken for the relief of acute or chronic suppuration, the broad rule applies: No acceptance until the discharge has been completely arrested.

Burger and Treitel have pointed out that high degrees of deafness may follow the radical operation, particularly if this has been performed on both sides, and that this deafness exposes the individual to the danger of accident, which danger must be considered in accepting the risk. Florschutz of the Gotha Life Insurance Company states that it is immaterial whether deafness has remained or not, since the company does not take account of all possible accidental dangers. In the case of operations undertaken for lupus or for a malignant growth of the outer ear the applicants are generally rejected, even though the disease has been circumscribed, and even though several years have passed without a recurrence.—"Handbuch der speziellen Chirurgie des Ohres und der oberen Luftwege."

Rheumatism in Relation to Social Condition and Occupation.—A. Grotjahn states that the rheumatic diseases have not received sufficient attention from pathologists, owing partly to the scarcity of anatomical lesions and partly to the slight menace to life in all cases excepting the acute infective forms and their sequelæ. Nevertheless, the rheumatic diseases, even in their mildest manifestations, have an eminent social significance, since they are the most common of disorders and for a longer or shorter time disable a countless number of individuals. Arthritis deformans with its crippling effects must be considered apart from the ordinary rheumatic affections. Particularly lamentable are the effects of this polyarthritis in individuals belonging to the working classes. The older clinicians were so impressed with this association that they designated the entire clinical picture as arthritis pauperum; although this disease is found in all classes of society, nevertheless the helplessness and misery accompanying it are most conspicuous among the poor. According to the Leipzig morbidity statistics, among 100,000 males who were insured and who were observed for a period of one year there were 590 cases of chronic articular rheumatism, of which four ended fatally, and there were recorded a total of 19,020 days of illness. Among a similar number of insured women there were 277 cases of chronic rheumatism, with two deaths, and a total of 9,970 days of illness. Classified according to occupation, the figures obtained for 100 cases of muscular and articular rheumatism were as follows:

	Age 15 to 34	Age 35 to 54
Stone masons	4	8
Brewery employees	4	12
Cement and lime workers	10	20
Employees in paper factories	7	11
Employees in wood industries	4	7

These figures show the greater morbidity at the higher age period, which is also the case in other social groups.

Articular rheumatism is responsible for considerable invalidity. In 1,000 cases of illness in men there were 62 cases of articular rheumatism and gout, while for women the figures were as high as 85. Muscular rheumatism, in spite of its relative harmlessness, incapacitates yearly an enormous number of individuals. The Leipzig statistics show that of 100,000 males observed for one year there were 3,316 cases of muscular rheumatism with a loss of 59,099 days of work. The figures for women were 1,816 and 38,708 respectively.

The nature of the rheumatic diseases is still almost completely veiled in obscurity, and the measures that have been taken to combat them are of doubtful efficacy. Rheumatic diseases are fairly evenly distributed throughout the different classes of society, so that it would appear as if the etiological factor is to be sought in some unknown constitutional predisposition. But the working classes suffer relatively more than the well-to-do, because of the absolute dependence upon the functional integrity of the muscles and joints.—"Soziale Pathologie."

Surgical Diseases of the Larynx in Relation to Life Insurance.—F. Ropke quotes Florschütz to the effect that life insurance companies look with suspicion on applicants who have been operated upon for neoplasms of the larynx. Even applicants who have been operated upon for new growths of the vocal cords, even though these have been proved to be benign both clinically and on pathological examination, must be subjected to prolonged postponement. If, after this time, the diagnosis of benignancy is confirmed, the risk may be accepted. Previous operations performed for acute diseases of the larynx furnish ground for rejection only if pronounced stenosis has remained. It goes without saying that applicants who have been operated upon for tuberculous disease of the larynx must be rejected—"Handbuch der speziellen Chirurgie des Ohres und der oberen Luftwege."

SECTION ON PEDIATRICS.

Stated Meeting, Held March 14, 1912.

DR. WILLIAM SHANNON IN THE CHAIR.

Intestinal Implantation of the Bacillus Lactis Bulgaricus in Certain Intestinal Conditions of Infants, with Report of Cases.—Dr. RALPH OAKLEY CLOCK read this paper, in which he stated that he had used buttermilk as a dietetic treatment for malnutrition, enteritis, etc., but that the results obtained had not been notably favorable. The beneficial effects of buttermilk as an infant food had been due to the large amounts of soluble proteid furnished in a finely subdivided form. The *Bacillus lactis bulgaricus* had been found to exert a most pronounced effect upon the putrefactive bacteria and was the only lactic acid bacillus known that would survive ingestion, reach the large intestine, and continue to live there creating nascent lactic acid. The author had experimented with various preparations supposed to contain the *Bacillus lactis bulgaricus*, but secured no definite results; most of the preparations on the market consisted of paralactic bacilli. A pure culture of the *Bacillus lactis bulgaricus* had been imported through Johns Hopkins Hospital and this culture was dried and mixed with milk sugar and compounded into a tablet. The writer reported the results obtained with this new method of treatment in bottle-fed babies. Although some of the cases were of the most severe type of gastrointestinal disturbance, a decidedly favorable result followed in every case. The gastric symptoms quickly disappeared, the toxemia subsided, and the mucus and blood disappeared from the stools. The indigestion was relieved and the stools became normal on the third or fourth day and no return of the intestinal condition followed in any case. The treatment consisted solely in the administration of the tablets containing the pure culture of the *Bacillus lactis bulgaricus*. The good results obtained by this treatment encouraged the writer to continue this treatment without changing the diet and thus test the reliability of the bacilli as a means of combating the intestinal putrefaction. The writer summarized as follows: The cases varied in age from five weeks to ten months. There were two cases of enterocolitis, 20 of gastroenteritis, five of which were mild, nine severe, and six toxic. The duration of the gastroenteritis was of from one to five days' duration prior to instituting treatment in the mild forms, from one day to two weeks in the severe types, and from one to two weeks in the toxic forms. The two cases of enterocolitis had resisted other methods of treatment, but quickly responded to the implantation method, and a decided improvement followed in every case within twenty-four hours after beginning treatment. By the end of a week, in spite of previous loss the weight had increased, on an average, four and one-half ounces. There was not a single failure or relapse. One of the great advantages of this method was that it was not attended by any untoward effects. Twenty tablets had been given in twenty-four hours to infants five or six weeks of age. Another advantage of the method was that it did not interfere in any way with the diet of the baby. The diets used during the treatment consisted of condensed milk, top milk formulæ, modified milk with Mellin's food, whole milk and barley water, peptonized milk, whey and dextrinized gruel, and modified milk with milk sugar. Vomiting invariably subsided on the second day. This was explained by the fact that after the putrefactive process in the intestine had been controlled, the reflex action in the stomach quickly subsided. The temperature which had been present in all the cases of toxic gastroenteritis and in the enterocolitis cases quickly dropped to normal under the implantation treatment. After the stools became normal, the dried culture was administered three times daily for a period of one or two weeks. The negative results previously obtained were unquestionably due to the small number of the true *Bacillus lactis bulgaricus* present in the tablets. The results obtained were entirely due to the action of the *Bacillus lactis bulgaricus* as no other therapeutic measures were employed, nor was the diet altered in any case.

Dr. WALTER LESTER CARR said that the paper was interesting because it contained many clinical suggestions. Buttermilk was valuable for a short time in feeding these babies, but then it became necessary to increase the number of calories by adding milk or cream. They had been making progress during the past few years in the use of the lactic acid bacillus and better results were being obtained. He could not, however, see any particular reason for continuing milk, a culture medium, when it was the source of the trouble. Some babies had an idiosyncrasy for milk when they were suffering from intestinal infections. He believed that the food that caused the disturbance should be cut off. The author of the paper had stated that the time required to treat these babies was about one week; in most cases the period was shortened by omitting the milk diet. Many cases would improve when only water was given after the intestines and stomach had been cleaned out. Dr. Carr was willing to assent to beginning the treatment of subacute and chronic cases with the lactic acid bacilli and with a limited quantity of milk, but he could not subscribe to the continuance of a diet that was the cause of the infection in an acute case. At the present time it was a difficult problem to get the best cultures; this was now a commercial affair and many of the preparations on the market did not come up to the standard.

Dr. THOMAS S. SOUTHWORTH said that at the present time their ideas might be said to be in a state of flux concerning summer diarrheas. They had two schools, those who would stop giving proteids and give carbohydrates, and those who would eliminate the carbohydrates and give massive doses of protoid casein; to these was added Dr. Clock's view that they might continue the customary diet provided they implanted lactic acid bacteria in the intestines to crowd out the putrefactive bacteria, but it was possible that the transformation of the carbohydrates by the lactic acid bacilli might tend to prevent their being split up into by-products which were more irritating to the intestine.

Dr. L. E. LAFETRA said that the paper was very suggestive and that he admired Dr. Clock's courage in continuing the use of the high fat mixtures in these cases of summer diarrhea. It seemed to him that the length of time the babies were under the lactic acid bacilli treatment was rather long when one considered the results obtained. He believed that other methods might be employed in addition, especially changing the diet. Dr. LaFetra asked Dr. Clock about the loss of weight in these cases and also how the lactic acid bacilli worked when given in condensed milk, which contained so much cane sugar. It was difficult to understand the effect of these tablets on the vomiting in some of the babies. At the Babies' Hospital several years ago implantation of the lactic acid bacilli in the rectum was used in connection with pure cultures given by the mouth. The results of this treatment were so bad that it was not continued the second year. Dr. LaFetra's impression regarding the advantages of the lactic acid bacilli was a most favorable one, but he had not used the same sort of culture as Dr. Clock. His experience with the lactic acid milk had been fairly satisfactory, but his results with the use of lactone milk, made at the hospital, had not been so favorable. He had obtained the best results in diarrheal cases from the use of protein milk. One could use lactic acid milk, made with pure cultures of the *Bacillus lactis bulgaricus*, and get good results in these cases.

Dr. GODFREY R. PISEK said that about five years ago he advocated the use of lactic acid bacteria in the treatment of diarrheas in which there were so many of the intestinal flora propagated. Now, after a thorough trial, he believed more in the old-fashioned method of treatment with calomel, castor oil, and the use of the temporarily restricted diet. Such a trial as Dr. Clock had made might be possible in hospital wards where scientific data could be obtained. He was surprised at the uniformly good results obtained which he would not have thought possible except in private practice. There was no doubt in his mind but that he had obtained some beneficial results by the implantation method, not in acute cases, but in the subacute and chronic ones, such as ileocolitis. By giving large quantities of lactic acid bacilli to these infants who had been previously starved the intestinal flora became changed and this might give the child a greater chance to make a recovery.

Dr. RALPH OAKLEY CLOCK, closing the discussion, said that the reason he had not changed the diet in these cases was to test the reliability of the *Bacillus lactis bulgaricus* as a means of combating putrefactive changes in the intestine. He presented the paper simply to show the results of his preliminary tests. In answer to Dr. LaFetra's question regarding the loss in weight, the Cuban case of enterocolitis had lost nearly two pounds in four weeks previous to the time when he first saw the child; during the time that the patient was under treatment with the lactic acid bacilli there was marked improvement and gain in weight, though there was an initial loss of three ounces. The favorable result that followed in the case fed on condensed milk was explained by the fact that the *Bacillus*

acidi bulgaricus flourished best in a medium containing carbohydrate medium, and although the sugar was not the same as that used to introduce the bacilli into the system, the two organisms were not antagonistic. As to the rapidity with which the gastric symptoms were relieved, the lactic acid bacilli, of course, had no direct action upon the vomiting, but after the putrefactive process in the intestines had been controlled the gastric symptoms which were reflex subsided.

The Pathology and Treatment of Chronic Stenosis of the Larynx Following Diphtheria.—Dr. Henry Lowndes Lynah read this paper in which he considered six different types of chronic laryngeal stenosis following diphtheria. (1) The nervous type which was accompanied by a marked element of fear and in which there was often a marked spasm which made extubation difficult. Frequently when the tube was raised it would slip off the jaw of the extractor and be sucked back into the larynx. When the tube was finally removed there would be a violent spasm necessitating reintubation. This condition was overcome by anesthesia, though the spasm might recur when the patient awoke. (2) The type in which there was spasm without the nervous element, a condition which was due to long-continued wearing of the tube, causing a temporary functional disuse of the intralaryngeal muscles, especially the separators or abductors of the vocal cords, the posterior cricoarytenoids. This condition did not come on suddenly as in the nervous type but usually after the patient had been returned to the ward breathing naturally, when four or five minutes later a spasm would occur which would necessitate reintubation. The spasm might be delayed for several days or hours or it might come on during sleep. (3) A type with marked polypoid growth at the base of the epiglottis and the ventricular bands, which fell together as the pressure of the tube was released and caused obstruction which might necessitate immediate reintubation. Clinically this type simulated the spasm type. These patients would breathe under anesthesia, though with difficulty. (4) The hypertrophic subglottic type, in which the stenosis was slow and gradual and which was accompanied by both inspiratory and expiratory dyspnea, and made reintubation necessary sooner or later. The contraction in these cases usually occurred at the cricoid cartilage and it might involve the entire lumen of the larynx. These slow contracting hypertrophic types were very difficult to reintubate and it was extremely dangerous to wait until grave stenosis supervened. (5) The cicatricial type, which was due to traumatic or surgical interference embraced the following classification: (*a*) Tracheotomy made imperative when it was impossible to intubate or when false passages had been made at the primary intubation; (*b*) tracheotomy to save life in the persistent autoextubation stage or in the extreme grade of hypertrophic contraction; (*c*) cicatrices resulting in chronic tracheal cannula cases, accompanied by atresia of the disused larynx above the cannula, and by polypoid hypertrophy about the cannula and on the posterior wall; (*d*) laryngotomies for the purpose of dissecting the hypertrophic connective tissue. (6) The atrophic type occurred in a few cases which had recovered after long treatment, but suffered with thick sticky mucocrusts which obstructed the larynx. In this type there was loss of voice and an extreme grade of dyspnea. The basis for the pathology of this condition was laid in the beginning with the acute diphtheritic exudation and the primary intubation. The tube virtually acted as a foreign body causing pressure on the laryngeal soft parts and as it rode up and down or anteriorly and posteriorly under the acts of coughing and swallowing, ulcerations were produced which added to the necessity for prolonged intubation. When these pressure ulcerations were of sufficient degree and occurred at the cricoid cartilage they caused necrosis with absorption of the whole of the cricoid ring with the frightful sequelæ of persistent autoextubation. Any involvement of the recurrent laryngeals was extremely rare. This autoextubation stage was one of the most frequent causes of subacute and chronic cases, and were it not for pneumonia, which usually carried off these patients, the percentage of chronic stenosis would be considerably greater than one per cent. The cicatricial types seldom occurred singly, and all required prolonged intubation in order to effect a cure. For the nervous and spasm types an extremely narrow-necked tube should be used that would allow for lumen. Dr. Lynah said that he had devised a tube by taking out the posterior portion below the head directly into the lumen; the patient was thus enabled to breathe and at the same time medicine was given to the cords and allowed the posterior cricoid arytenoid muscles to work by taking pressure off the muscle. When polypoids were the cause of spasm, a wider necked tube would have to be substituted in order to press out these masses. A tube with a large head was also necessary. For the hypertrophic type gradual dilatation with special tubes measured in millimeters with increasing diameters should be used. The tube should dilate antero-posteriorly as well as laterally; the writer's cigar-shaped tube accomplished this purpose. In some cases excessive dilatation would cause spasm. The treatment of the cicatricial type was also by dilatation, though when the tracheal fistula was low a special tube with the greatest diameter from the retention swell downward should be used. In cases of chronic stenosis from long wearing of the cannula and closure of the larynx above, dilatation should be accomplished from the tracheal fistula upward by means of sounds and then a suitable dilating tube introduced. The tube used in these cases should be a post tube which had a device that could be screwed into the tube to prevent its being dislodged during the act of coughing. The tracheal fistula should be curetted and all polypoid growth removed, the edges scarified and the wound closed about the post. This tube should then be worn for a month when it should be changed for a larger dilating tube. The author had abandoned laryngotomy in these cases for the reason that this operation added a pure cicatrix to the already complicated pathology. He had had fairly good results with these cases, though, owing to infection, the healing of the wounds was usually by granulation. The atrophic type with the thick mucous crusts should be treated by intralaryngeal medication after a cure had been effected. For this purpose he used Mandel's solution, iodine petrogen, or the internal administration of the iodides and steam inhalations.

Dr. William P. Northrup said he was present because he thought he was the oldest living intubationist. He said that he was doing autopsies at the Foundling Hospital at the same time that Dr. O'Dwyer was perfecting his intubation tubes, and he told of his association with Dr. O'Dwyer in this work. At that time Dr O'Dwyer, Dr. Brown, and Dr Northrup were the only ones doing intubation work. He had had the honor of reading the first paper on the subject, written by Dr. O'Dwyer, before the British Medical Association. Dr. Northrup expressed himself as greatly edified by the work done by the writer of the paper and said he felt that they all appreciated the value of this work.

Dr. John Rogers commended Dr. Lynah's work along this line. He said that few men understood the cause and the treatment of laryngeal stenosis. He thought that all of these cases could be cured by this treatment and that no case of stenosis of the larynx should be given up as hopeless. His experience with the metal tubes led him to look upon them as more or less dangerous, owing to their tendency to become coated with calcium material and to occlude the tube. He thought the time mentioned for treatment by Dr. Lynah was rather short. Where fibrous structures were involved he thought an average period of two years was sufficient.

Dr. Ira Van Gieson, referring to the inferior laryngeal nerve, said that its neurilemma would stand a certain amount of pressure and would accommodate itself to this pressure. However, in these instances there might be some lesion of the intramuscular twigs of this nerve while the condition of the trunk would be intact. The theory advanced by Dr. Lynah was excellent, but these were facts that should be taken into consideration.

Dr. Lynah, speaking in regard to the duration of his treatment of these cases, said that there must have entered an element of luck. Much had been written regarding the pathology, but nothing he had read had been to him at all convincing. It was a fact that the cricoid cartilage was the cause of the real trouble in these cases and not the condition of the vocal cords.

MEDICAL ASSOCIATION OF THE GREATER CITY OF NEW YORK.

Stated Meeting, Held March 18, 1912

The Vice-President, Dr. Ransford E. Van Gieson, in the Chair.

Removal of Uterus and Vagina for Complete Prolapse.—Dr. Herman J. Boldt presented a uterus and vagina removed four days previously from a patient 58 years old who, notwithstanding her advanced age, was compelled to undergo much physical exertion. Unlike most sufferers from this condition, she was the subject of considerable vesical disturbance. During the first two days the patient complained of hypogastric pain, which, in Dr. Boldt's experience, was unusual after such operations. At the present time she was doing well, and was up and about.

Ovarian Cyst with Complete Twist of the Pedicle.—

Dr. Bovee presented a second specimen, an ovarian cyst removed two days previously. The tumor, which was attached to the left ovary, had extended two fingers' breadth above the umbilicus. The interesting feature in connection with the specimen was that a complete twist of the pedicle existed without the patient's having symptoms. The tumor showed the effect of the twist in the dark color of its contents and the appearance of its walls. Yet the patient stated that she was entirely free from pain, nor was there any pain upon palpation of the abdomen when she was examined.

The Treatment of Bleeding from Gynecological Sources.—Dr. Bovee, in this paper, said that before deciding on any treatment it was necessary to first ascertain the source of the hemorrhage; otherwise one could not correct the condition intelligently. Commencing with external sources of bleeding, he mentioned varices, which he said, were a cause almost exclusively in pregnant women. Sometimes the hemorrhage was very profuse, and in two instances which he had met with the patients were almost exsanguinated. Here inspection at once showed the condition. Aside from pregnancy, bleeding could occur only from injury to a vein. This might result from scratching, and he had seen one case of this kind. Bleeding from erosion or ulceration of the vagina caused by pessaries could usually be remedied by the application of a silver nitrate solution after removal of the pessary. Having referred to bleeding in connection with senile atrophy of the vagina, he went on to speak of that due to carcinoma in this situation. Here the treatment would depend on how far the growth had advanced at the time of its discovery. If this was early, complete removal would be indicated; where this was impossible, palliative treatment. Thorough curetting should be done with a sharp curette, and afterwards acetone or iodine applied. Slight bleeding from the vaginal portion of the cervix, due to erosions, might occasionally occur after sexual intercourse, and was best treated by the application of a ½ of 1 per cent. solution of silver nitrate. Between syphilitic and tuberculous ulcerations it was difficult to distinguish except with the aid of the microscope. In the former, after the bleeding had been stopped by tamponing, specific treatment should be instituted. In tuberculous ulcerations the treatment was by curetting, followed by the use of the galvanocautery, if the ulcer were confined to the vaginal portion of the cervix. Myomata of the cervix were sometimes a source of hemorrhage. If large, their extirpation was a serious operation. If small growths were allowed to remain, the best treatment consisted of the use of copious hot douches and the internal administration of hydrochloride of cotarnine or ergot. To stop the bleeding from lacerations of the cervix resulting from delivery (the diagnosis of which could be made upon inspection and with the use of retractors) all that were necessary were one or two sutures. Hemorrhages from the body of the uterus might be divided into two classes, those in which the organ was of normal size and those in which it was enlarged. In the first of these was profuse menorrhagia without any definitely assignable cause, and this he was accustomed to treat by means of a strip of gauze medicated with 10 per cent. carbolic acid, and wrapped about an applicator syringe, which, after its introduction into the uterus, was pushed off with a forceps and allowed to remain for 12 hours. This plugging was removed by means of a string left attached to the gauze. In the second class we had hyperplasia of the uterus, which was first described by Pallea, some thirty-five years ago, under the name of "Fibrosis of the Uterus." In many of the cases nothing could be found in the endometrium. A good plan of treatment was the local application every third, fourth, or fifth day of pure phenol impregnated into an intrauterine gauze tampon, which was allowed to remain in the uterus for from eight to twelve hours. In obstinate cases a few drops of a 50 per cent. solution of zinc chloride might be employed in place of the phenol, an alkaline powder, as bicarbonate of soda, being used in the vagina to prevent corrosive action by any of the solution escaping from the uterus. For inflammatory conditions of the endometrium, curetting, followed by suitable local applications was of service. In the case of submucous myomata and of polypi of the uterus it was often almost impossible to make a diagnosis when these were of small size. When this could not be done otherwise, it was advisable to split up the cervix and make a digital exploration. If a moderate sized polypus were found, the cervical incision usually sufficed for its removal; if a myoma, the incision was extended, and the growth enucleated. Hydatid moles gave an impression of elasticity, feeling somewhat like a tight balloon to the touch. In ectopic gestation immediate operation was usually called for, and abdominal incision was always to be preferred to the vaginal. In premature separation of the placenta the patient was attacked with sudden faintness, sometimes amounting to collapse, and there was a rapid increase in the size of the uterus. The indication was to empty the latter as quickly as possible. In placenta prævia, where this was marginal, the patient, with the exercise of special care, could usually be carried to full term; but if it were central, or nearly so, the emptying of the uterus was called for. Sometimes we had to make use of tight tamponing until dilatation of the cervix could be accomplished, while in some cases vaginal or even abdominal cesarean section was indicated. When there was atony of the uterus, Momberg had recommended constriction of the trunk with rubber tubing, on the principle of the Esmarch bandage. If the patient had any heart trouble, however, this procedure was contraindicated. A myomatous uterus could be diagnosed after the expulsion of the child by means of bimanual examination. In rupture of the uterus if the rent were small, and the child still in the uterus, loose tamponing was preferable to abdominal section. With a large rent, abdominal section was imperative.

Observations Based Upon a Study of 139 Cases of Induction of Labor with the Modified Champetier de Ribes Bag.—Dr. George L. Brodhead, from a study of these cases gave the following general results. 1. Sizes Nos. 2 and 3 of the bag were most useful. 2. Accidental rupture of the membranes occurred in only 3 per cent. of the cases. 3. The great value of the bag was shown by the fact that in 90 per cent. of the cases labor was induced by the use of not more than two bags, while in nearly 70 per cent. one bag was sufficient. In only 6 per cent. was labor not induced by the bags; three of these cases being in private work and three in hospital. 4. Anesthesia for bag introduction was usually unnecessary, as shown by the fact that an anesthetic was used in only 14 per cent. of private cases and 16.6 per cent. of all cases, including hospital cases where the anesthetic was deemed advisable for clinical purposes. 5. In 31 per cent. of cases labor began at the time of the introduction of the first bag; in 70 per cent. within 12 hours after the insertion of the first bag, and in 88 per cent. within 30 hours of this. 6. The average length of time between the insertion of the bag and the onset of labor was, in primiparæ, 8 hours and 22 minutes; in multiparæ, 10 hours and 22 minutes, and in all cases, 9 hours and 41 minutes. 7. In all primiparæ the average duration of labor induced by the bag was 22 hours 9 minutes; in all multiparæ, 15 hours 52 minutes; in all cases, 18 hours 2 minutes. 8. Forty-nine per cent. of labors terminated normally and 70 per cent. normally or with the low forceps operation. 9. In 5 per cent. of cases the presentation was changed, but in only one case was the outcome affected because of this accident. 10. In 6 of the 139 cases, or 4.3 per cent., the cord presented or prolapsed, but it was to be remembered that in 63 cases labor was induced for contracted pelvis, relative disproportion, or hydromnion, and that, therefore, the accident, under any circumstances, was much more liable to occur. 11. The morbidity in private work was practically nil, and in hospital work very slight. 12. In private work the fetal mortality was about 5 per cent.; in hospital work, 11 per cent. This difference could be partly explained by the fact that private patients naturally received more individual attention, and necessarily the results were correspondingly better. 13. The maternal mortality from the use of the bag was nil. Dr. Brodhead described the technique of the introduction of the bag, and stated that of the 139 cases, 75 were at, or beyond, full term, 53 between 8 and 9 months of pregnancy, 8 between 7 and 7½ months, and 3 between 6 and 6½ months. The two chief causes for which labor was induced were contracted pelvis (41 cases) and toxemia, including albuminuria, nephritis, and eclampsia (27 cases). In one of the cases in private work in which the bags were not successful the cervix was dilated up to four fingers by means of two bags; then, as there were no pains, an attempt was made to introduce a bougie, which resulted in the accidental rupture of the membranes. Labor began in about two hours and the patient was delivered normally after a five-hour labor. In this instance the use of the bags undoubtedly greatly shortened the labor, although pains were not induced. In another case two bags dilated the cervix up to three fingers, but no pain followed until the expiration of a number of hours, when the membranes ruptured and labor began. The third case was that of a patient who had eclampsia at about 6¼ months. A bag was introduced into the uterus, and although traction was made intermittingly for some eight hours, no effect was produced. This patient was delivered by version, after *accouchement forcé*. The series of 139 cases included 75 private and 64 hospital or outdoor patients, while 48 of the women were primiparæ and 91

multiparæ. Of seven cases in which change of position occurred after bag introduction, four were in private and three in hospital patients. In the first of the private cases the position changed from L. O. A. to breech, and then to transverse, and the patient was delivered by podalic version. In the second case it changed from R. O. A. to transverse. By external version the vertex was brought over the brim of the pelvis, when the membranes were ruptured, and one hour later normal delivery took place. In the third case the change was from L. O. A. to transverse, and the same procedure was successfully employed. About twelve hours after the artificial rupture of the membranes the patient was delivered by the median forceps operation. In the fourth case a breech presentation became a transverse, but after this had been converted into R. O. A., normal delivery occurred. In one of the hospital cases, in which the child was stillborn, the change of position, from vertex to breech, was considered responsible for the death of the child, which was delivered by breech extraction. While, except in this instance, the change in presentation made no difference in the outcome, the speaker said that the possibility of the accident should be kept constantly in mind when one was using the bag method. In one of the 139 cases a curious accident happened, though fortunately no harm resulted. The patient was a multipara, and labor was induced at eight months for flat pelvis. At 12:30 p. m. a No. 3 bag was introduced, and one hour later the membranes ruptured spontaneously. No labor pains occurred, and when at 3:30 the following day the patient was examined, it was found that the bag had slipped up into the uterus, above the child's head. Traction upon the stem brought the bag down into the cervix, the first stage began at 4:30, and labor was completed normally in three hours. This accident would not have occurred if the stem had been tied to the vulva pad, as was the usual practice.

Septic Puerperal Infections.—Dr. JOHN O. POLAK read this paper. Puerperal infection, he said, was a wound infection, due to the entrance of organisms into wounds of the genital tract. It was primarily a local inflammatory lesion, which might or might not be attended by an invasion of microorganisms or their toxins through the lymphatic or vascular channels. When the invasion did take place we had a bacteriemia or an intoxication. If the patient recovered, it was because she was capable of overcoming and destroying the infecting agent. When we remembered that in the puerperal woman microorganisms were present at the vulvovaginal orifice, in the vagina, in the cervix, and even in the uterus itself, and that in a primipara the vulvovaginal orifice was almost invariably lacerated to some degree, that the vagina was frequently torn in the course of operative labors, and that the cervix remained for nearly three days a shapeless, traumatized, devitalized curtain, with its margin torn at many points, it was no wonder that infections took place. In his experience the high mortality in general practice, and especially the morbidity in puerperal sepsis, was produced by medical men, and was due to insufficient disinfection of the hands, together with a tendency to undertake operative delivery, often in the absence of any absolute indication, before complete dilatation of the passages was obtained. From midwives there was less trouble of this kind, for the reason that they did not attempt operative procedures. The primary focus in almost all postpartum and postabortal cases was within the uterus. An acute endometritis always involved the contiguous uterine muscle, with a resulting lymphatic metritis. Infection of the placental site resulted in a thrombophlebitic metritis, a dissecting metritis, an abscess in the uterine wall, or a thrombosis of the femoral or pelvic veins, with local or remote foci. Tubal infection, with resulting suppurative salpingitis, might be a complication. Fortunately, unless the infection were a mixed one in which the gonococcus played a chief part, tubal extension and ovarian involvement were comparatively rare. More frequently the infection extended, through the torn cervix, to the broad ligament cellular tissues, with a resulting parametritis; or a peritonitis might develop from extension by the lymphatics or through the tubes. Whether the infection was circumscribed or general depended on the variety and virulence of the infecting cocci and the quality, as regards resistance, of the soil into which they were introduced. When organisms were virulent, extension took place through the lymphatics or the blood channels. Lymphatic infection led to lesions in the uterine walls, pelvic connective tissue, or peritoneum. If the organisms invaded the capillaries and small vessels directly, a general blood infection would result, either as a septicemia or a bacteriemia. If they proliferated in the venous thrombi they were apt to be carried thence in septic emboli to various parts of the body, producing metastatic foci. Each case of puerperal infection should be studied individually, and an accurate diagnosis be made on the clinical, bacteriological and blood findings before any treatment was instituted. In this examination we should determine, first, whether the infection was confined to the genital canal; second, the site of the local lesions, whether in the uterus or beyond it; third, the nature of the intoxication present; fourth, what natural or individual resistance the patient had. A well-contracted uterus, with a closed cervix, should not, of course, be entered, but under other conditions a digital exploration should be made of the interior of the uterus to ascertain its contents. In putrid or saprophytic endometritis associated with a decomposition of the placental tissues, secundines, or blood clots within the cavity, and which produced general symptoms essentially toxemic in character, the uterine contents might (in pregnancies after the seventh week) be removed with the finger or a placental forceps. When the finger had demonstrated that the cavity was empty the uterus should be firmly packed with sterile gauze which previously had been soaked in pure tincture of iodine and squeezed to remove the excess of the latter. This pack was to be left in position for from twenty to thirty minutes, and after its removal no further intrauterine instrumentation or medication should be resorted to. If the cervix were found open and the body of the uterus empty and well-contracted, and if the endometrium were smooth, as was often the case, three or four days after delivery, the digital examination might be followed by a single intrauterine douche of normal salt solution. The principles of the treatment after the condition of the uterus and the extent of the adjacent local lesions had been determined might be summarized as follows: First, the destruction of the infecting organisms, or the diminution of the force of the invasion, at the site of the primary infection; second, stimulating the resisting power of the patient; third, the destruction of organisms in the blood stream; fourth, operative measures. In carrying out the first of these principles efficient drainage was a most potent factor, and it was therefore urged that the bed should be so raised that the patient would be kept in the Fowler position. In reinforcing the resistance of the patient, in addition to food and stimulation, fresh air and sunlight were of very great practical value. For the third point considerable reliance could be placed on vaccines. Polyvalent vaccine should be administered at once, and later autogeneous vaccines, which might be repeated at such intervals as the existing conditions indicated. Any operative measures which might be undertaken would, of course, be dependent upon special indications present. In conclusion, the speaker gave expression to certain axioms and mentioned certain observations which had guided him in the management of septic cases. Some of these were the following: Any intrapelvic or intrauterine manipulation made during the acute stage of a puerperal or postabortal sepsis always broke down and disturbed nature's protective barrier and permitted of the dissemination of the infection through freshly abraded or penetrated surfaces. He had learned from experience that the endometrium should never be curetted in streptococcic infection; it was only necessary to have drainage and firm uterine contraction, as the germs would be cast off with the necrosis and expulsion of the decidual remains. The curette here was distinctly mischievous, breaking down the protective wall and allowing the streptococci to penetrate the musculature and reach the parametrium and peritoneum. The danger from curettage became increased as the period of pregnancy advanced, and under no circumstances should the placental site be curetted. Digital exploration was the most rational method of learning the contents of the uterus, and instrumental evacuation of the contents of the cavity should be limited to pregnancy of eight weeks or under. After the uterus had once been thoroughly emptied the pelvis should be left absolutely alone, except for postural drainage, while every effort should be made to support the patient and increase her natural blood resistance. Exudative pelvic peritonitis might be considered as a sequel of untreated or badly treated endometritis. In the majority of instances nature was competent to localize and circumscribe the infection. Thrombophlebitis was a conservative process on the part of nature, and manipulation or examination tended to break off infected emboli and disseminate the infection to remote parts of the body. Enormous pelvic and abdominal exudates might disappear without operation, and in time enlarged ovaries, tubes, etc., were likely to resume their proper size and functions. As long as the patient's general condition improved, no surgery was advisable. If the blood serum was sterile, and the blood showed a leucocytic resistance to the infection by a relative white cell increase, the prognosis was favorable, no matter what form of cocci was found in the uterine cavity. A local exuda-

tive focus should never be disturbed postpartum as long as the patient was showing signs of improvement, unless there was definite evidence of a localized collection of pus. When such was the case the opening made should be by extraperitoneal incision. Extraperitoneal drainage of local foci should be chosen when possible, either by means of an incision just above Poupart's ligament or posterior vaginal section, and when this was impossible because of inability to determine the exact anatomical relations of the local foci, an exploratory laparotomy was justifiable in order to make an accurate diagnosis and determine upon the safest route for drainage. All operations were attended with less risk after the acute stage of the infection had subsided. Inoculations with autogenous vaccines would promise prompt results in staphylococcic and colon bacillus infections, but in that from the streptococcus, vaccine treatment was unreliable, being of value only when the virulence of the germ was attenuated or when nature had already developed some phagocytic defense.

Dr. HENRY C. COE said that it seemed to him that the tone of the papers which had been presented was too dogmatic. Experiences undoubtedly varied. Certain conditions which Dr. Boldt had described, and their treatment, were well recognized; but we met with many cases of hemorrhage, particularly in young women, which were dependent upon no condition that we were able to determine. In some such cases he had tried ligation of the uterine arteries, but this procedure had not proved of permanent value. In every instance the hemorrhage had recurred, and in one or two cases he had resorted to hysterectomy. He fully agreed as to the value of splitting up the cervix for making the diagnosis of myoma or polypus of the uterus. These were cases which gave great trouble to the general practitioner. As to the use of the modified de Ribes bag, he had not had the favorable experience of Dr. Brodhead, and he always approached this little operation with some degree of trepidation. While his mortality among the mothers had been nil, his percentage of deaths in the children was larger than that given in the paper, and in this connection he narrated two cases where the children were born dead. He conceded, however, that in some instances this method of inducing labor was essential. He could not altogether agree with some of Dr. Polak's contentions. At Bellevue Hospital they had many cases of sepsis following criminal abortion, and in most instances of this kind nature had built up such protective walls that they had no hesitation in invading the exudate present. He approved of Dr. Polak's conservative stand in regard to curetting and douching, believing his objections well taken. On the whole, however, Dr. Coe thought the reader of the last paper was somewhat too optimistic in his views.

Dr. J. CLIFTON EDGAR said he had employed Momberg's belt in three cases, and they had given him a warning. It required the utmost care to prevent syncope when the belt was withdrawn, as it caused enemia about the heart. He agreed with Dr. Polak that the physician was more apt to be responsible for puerperal sepsis than the midwife. His observations at the Jewish Maternity Hospital, where he was consulting obstetrician, had convinced him of this. He also agreed that polyvalent serum should be administered at once, on account of its sustaining effect, which gave a chance for the formation of antibodies. Autogenous vaccines could be given after the diagnosis had been established. Dr. Brodhead's experience had led him to prefer the use of the modified de Ribes bag to other methods, and probably most of us had also come to the conclusion that it was preferable. Some, however, advocated Krauss's method of introducing a catheter. As to the size of the bag or bags to be employed, he thought that Dr. Brodhead had taken the right position. While the Nos. 2 and 3 bags were not as efficient as the larger ones, with them there was less danger of a change in the position of the fetus occurring than when the larger 4 and 5 were used. The beginner in this method was apt to rupture the membranes, but with proper care there was but little risk of this. The bivalve speculum should be employed when making the introduction, and he rarely found it necessary to give an anesthetic, even in his clinic at the Manhattan Maternity. When the cervix was not sufficiently dilated to admit the bag, Krauss's method might be used, or gauze introduced, for causing dilatation. He did not believe in doing any injury to the cervix. While the uterus had been known to be ruptured by a Barnes bag, he had never seen any harm result from the rupture of a modified de Ribes bag. As to the life of such bags, some tests which he had made showed that four boilings were about all they could stand.

Dr. AUSTIN FLINT, JR., discussing the question of the induction of premature labor, said that the crux of the matter hinged on two points, namely, first, the period of pregnancy at which it was done, and, second, the condition of the cervix, irrespective of the period of pregnancy. Bags worked well in favorable cases, but not in unfavorable ones, where the time was more than a month before term or where there was a long, hard cervix. Here it was advisable to temporize, if possible, by introducing a bougie or leaving a gauze tampon in position for twelve hours or more before resorting to the use of the bag. The indications for employing the latter should always be borne carefully in mind. Unfortunately, however, these bags were now being more and more used for insufficient causes. So, too, was cesarean section done too frequently, and this was all wrong. He believed that Dr. Polak was right in urging that early exudates should be left alone; later we could open up freely. The use of iodine, as practised by him was new to him (Dr. Flint). Personally he had been in the habit of employing alcohol.

Dr. RALPH W. LOBENSTINE said that in the induction of labor in a primipara, with the cervix long and tough, and undilated, he did not think bags were as satisfactory as the introduction of the bougie into the uterus, combined with tight vaginal tamponage. In all other cases he was an ardent advocate of the rubber bag. He agreed with Dr. Flint that at the present time the induction of labor was practised entirely too frequently, and without adequate medical reasons. In resorting to this procedure in the case of a muscular woman, especially a primipara, with only a moderate pelvic dystocia, one should always keep in mind the fact that the unyielding cervical muscle, when nature had not as yet prepared it for labor, might cause more actual difficulty than the dystocia. After the complete premature rupture of the membranes he believed in starting up labor within 24 or 48 hours, as a longer delay would increase the dangers to both mother and child. One point of caution—when the bag was being filled one should always remember the possibility of pinching the cord. Speaking upon Dr. Polak's paper, Dr. Lobenstine said that the digital intrauterine exploration was undoubtedly of great value, provided that it could be carried out aseptically and with the utmost gentleness. Personally, he had been using the tincture of iodine for several years in the class of cases mentioned by Dr. Polak, and had found it more satisfactory than alcohol. He firmly believed in the value of an exploratory abdominal incision in certain doubtful puerperal pelvic infections. Without this, in some instances, an exact diagnosis as between an extraperitoneal and an intraperitoneal condition, was impossible.

Dr. SAMUEL W. BRICKNER, having referred to the small number of Dr. Brodhead's cases (6 per cent.) in which the bags failed to induce labor, and discussed what was best to be done in cases of this kind, stated that in general his own experience had been much the same as that of Dr. Brodhead. Of late he had been trying the rectal tube, as advocated by Little of Montreal, and had found it exceedingly useful. In septic puerperal infections his experience with vaccines had been different from that of Dr. Polak. Both with polyvalent and autogenous vaccines his results had been practically nil—he had not observed any benefit whatever from their use. Patients might get well, however, whether these agents were employed or not; so that it was somewhat difficult to know what value to assign to them. In cases of puerperal infection he believed that, except for vital indications, such as the removal of pus, the less surgical interference there was, the better off the patient would be.

Dr. W. H. W. KNIPE mentioned a case of gynecological bleeding which evidently depended on too much alcohol periodically. The patient had passed the menopause and he expected to find carcinoma of the uterus; but a careful examination and the use of the curette revealed nothing whatever. An extended study of the case showed that the bleeding came on whenever she indulged too freely in stimulants. In inducing premature labor his own plan of procedure was to commence with a large soft-rubber tube, inserted in a zigzag manner, and finish up with the bag, and this seemed to work very well. His results with these bags had been good, and he had found nothing to take their place. In cases of puerperal sepsis he was accustomed to employ gauze saturated with Churchill's tincture of iodine (one-half strength), which he left in the uterus for two to three hours, and follow this up with a 70 per cent. solution of alcohol. His impression was that after the germs had once got into the blood-serum we could do very little either with vaccines or anything else.

Dr. BRODHEAD, in closing, said that the reason why he took up the use of the bag was because he had ruptured the membranes (a very undesirable complication) so frequently with the bougie. He regretted that Dr. Coe had expressed himself so pessimistically. It was only by the study of a large number of cases that we could arrive at

any definite conclusion. When eclampsia or other emergency was present he was accustomed to employ both the rectal tube and the bag, but ordinarily the latter was sufficient. He believed that if induction of premature labor were resorted to in all suitable cases cesarean section would be much less frequent than at present. Earlier than the eighth month, however, the latter operation gave much the better results.

Dr. Polak, in closing, said that he made use of iodine in only one class of cases, namely, where the decomposing matter within the uterus had been removed by the finger. He never employed it in streptococcic infection or where the endometrium was smooth. The special point that he wished to make in the paper was that in every case a complete blood count and blood culture should be obtained.

Books Received.

Menstruation During Pregnancy and Lactation.—A. Grosse believes that the so-called menstruation that sometimes occurs during pregnancy is really a hemorrhage, occurring at various epochs, often near the normal congestive period which would correspond to menstruation, and lasting for from a few hours to several days. The anatomical position of the ovum closes the uterine cavity in such a manner that menstruation cannot normally occur. Hemorrhage is caused by a separation of the ovum from the uterine wall, a pathological condition of the membrane resulting from low implantation of the placenta, or an endometritis. Lactation when efficiently established is never accompanied by menstruation. But menstruation does not necessarily impair the quality of the milk nor harm the child.—*Journal de Médecine de Paris.*

The Sweat Glands in Puerperal Infection.—S. Rebaudi, from a study of portions of skin taken from the axilla of cases that had died from puerperal infection, discovered a degeneration of the sweat glands concomitant with that found in the liver and kidneys. The predisposing cause of this condition is the puerperal state and the determining causes are toxins and the exalted virulence of the bacteria which, generally saprophytic, become virulent in cases of infection. All the emunctories of the body combine in an attempt to remove these poisons, and the sweat glands have an important part in this attempt. The result is a degeneration of the glands, beginning with vacuolization and ending with fatty degeneration and destruction of the epithelial lining. The same changes are found in all infected cases, the difference being only in the degree and not in the kind of lesion.—*Folia Gynecologica.*

Health Reports.—The following cases of and deaths from smallpox, yellow fever, cholera, and plague have been reported to the Surgeon-General, Public Health and Marine Hospital Service, during the week ended April 6, 1912:

REPORT OF A CASE OF ACUTE ENDOCARDITIS WITH RUPTURE OF ALL THE CHORDÆ TENDINEÆ OF THE ANTERIOR CURTAIN OF THE MITRAL VALVE.

By LEWIS F. FRISSELL, M.D.,

NEW YORK

ASSOCIATE ATTENDING PHYSICIAN ST. LUKE'S HOSPITAL; ASSOCIATE IN MEDICINE, COLUMBIA UNIVERSITY.

T. T., HOTEL MANAGER, 52 years of age, married, was admitted to the medical ward of St. Luke's Hospital, July 5, 1911, complaining of severe dyspnea. Until eight weeks before admission he felt perfectly well, but at that time noticed that his customary mode of life fatigued him and that he became short of breath on exertion. He has not noticed precordial pain or sudden exacerbation of symptoms. Gradually his dyspnea increased, confining him to bed, and of late has amounted to orthopnea. He has not been conscious of fever, but his wife thinks there has been some elevation of temperature in the last few weeks. There has been a little cough without expectoration. Urination frequent. His occupation required no severe physical work and his habits were inclined to be sedentary. Until the onset of his present trouble he had been remarkably free from illness since his childhood, in which he had suffered from measles, scarlet fever, diphtheria, and chicken pox. No history of venereal disease or rheumatic fever is obtainable. His personal habits are bad. He is a constant user of alcohol, five or six whiskeys or beers daily, with periodic sprees. Tobacco is used in moderation. Coffee, six cups daily. The family history is good; his father died of pneumonia and mother of apoplexy.

Physical examination: Patient is a fairly well developed and nourished man of 52 years, who appears moderately prostrated. There is some dyspnea and orthopnea. No jaundice or cyanosis. Skin and mucous membranes somewhat pale. Eyes: Pupils equal and react. Slight icteroid tinge to scleræ. Tongue: Moist, not coated. Pharynx normal. Teeth: In rather poor condition; a few missing. Neck: Visible venous pulsation. Chest: Well developed; expansion good. Heart: Lifting impulse general over precordium. At apex region is a thrill, diastolic in time. Diffuse visible and palpable apex impulse in fifth and sixth spaces, 5½ inches from median line. Left border 6½ inches out. Right border 2½ inches to right of median line. At apex heard over the whole precordium and transmitted to back is a loud systolic murmur, almost replacing first sound. This murmur has a maximum intensity at the apex; to left of sternum in fifth space, it is almost musical in character. Within nipple and to sternum a gallop rhythm is heard. Over base there is a soft systolic murmur. Both second sounds accentuated. Pulse: Regular, small, fair force, vessel wall palpable. Lungs: On right side posteriorly beginning just below scapula is slight dulness, increasing to base. At extreme base fremitus, voice and breathing sounds much diminished. An occasional râle heard at left base. Otherwise lungs are clear. Abdomen: Lax; liver percusses to free border, edge not felt, but liver region is somewhat tender on pressure. Spleen not palpable. No dulness in flanks. No masses. Knee jerks present. Considerable edema of lower extremities.

The day following admission there was noted a presystolic murmur of rather short duration but distinct crescendo character just within and above the apex, and at the apex a very faint diastolic murmur of a transitory nature as it disappeared not to reappear. The temperature was elevated, remaining between 102-101° the greater part of his stay in the hospital, but toward the end becoming subnormal. Repeated blood cultures failed to reveal the infecting organism. The physical signs in the heart did not change, though at one time the conduction time was increased owing to the effects of digitalis and the systolic murmur became more intense and musical. His hydrothorax and consequent dyspnea were several times relieved by thoracentesis, but after a long illness the patient died on October 5 of a terminal infarction of the lung. At no time did he complain of sudden, intense precordial pain nor did his dyspnea suddenly become aggravated.

Autopsy October 19, 1911, 2 P.M., by Dr. C. H. Bailey. Body of well-developed but emaciated adult male. Marked edema of hands, legs, and dependent portion of body. Slight general jaundice. Pupils, 3 millimeters, normal; conjunctivæ yellow. Peritoneum: About one liter of clear yellow fluid in abdominal cavity. Over anterior surface of liver, especially right lobe, are patches of firmly adherent organized exudate, also over surface of spleen, and a few patches on intestines. Firm adhesions join the omentum to the parietal peritoneum on the left side in the region of the splenic flexure and upper portion of the descending colon. Pleura: Pleural cavities contain together 2,300 c.c. clear yellow fluid. Somewhat more in right than left. Left lung firmly adherent at apex. Lungs: At the base of the right lung anteriorly is a roughly circular area of consolidation about 3 centimeters in diameter, deep red on section, slightly raised base surrounding surface, and with fairly sharply defined outlines. A branch of the right pulmonary artery leading to the right lower lobe is completely thrombosed. The thrombus extends from the root of the lung, where it protrudes into the auricle as a free tongue-like mass to the posterior portion of the left base. It completely plugs the vessel, is a little more than 1 centimeter in diameter at its upper part, is grayish in color with red mottling, and gen-

erally firm, but in places softened. The whole lung, especially the base, is congested and edematous, but the tissue surrounding this vessel shows no sign of infarction. No thrombosed vessel is found leading to the area of consolidation in the anterior portion of right base already described. Left lung: At left apex are two or three fibrous scars and one calcareous nodule about 2 millimeters in diameter. On anterior edge of upper lobe about 3 inches below apex is a roughly wedge-shaped area of consolidation, deep red on section, firm, and with rather sharply defined limits. At its apex is a thrombosed vessel about 3 millimeters in diameter. This thrombus is rather firmly attached to the vessel wall in places. A similar area is present in the anterior edge of the lower lobe. Pericardium: Contains about 50 cubic centimeters of clear yellow fluid. On surface of heart are numerous large irregular whitish areas of organized exudate, which are torn from the wall with some difficulty. The surface of these is generally smooth; one about 2 centimeters in diameter on anterior surface of left ventricle has an irregular, ragged surface.

Heart: Very large; weight, 570 grams. A tough grayish clot is firmly adherent to the musculi pectinati of the right auricle. Triscuspid orifice dilated 16.5 centimeters. Cusps normal. Pulmonary 11 centimeters normal. On opening the left auricle, the anterior cusp of the mitral, and its chordæ tendineæ are seen protruding into the auricle, the latter having been torn from their attachment to the muscles. On the auricular wall about 3 centimeters above the auriculoventricular orifice are a few small, rough, yellowish vegetations. The mitral orifice measures 14 millimeters. The anterior cusp, all the chordæ tendineæ of which are torn from their attachment to the heart wall, contain several nodular thickenings, but no recent process is apparent. The chordæ tendineæ attached to it are of apparently normal length, but enlarged, soft, and yellowish in color, and appear to have been recently ruptured. At the summit of the anterior papillary muscle is a small stump, which was evidently the point of attachment of one of the broken chordæ. There are two similar nodules in one of the cords of the posterior cusp near its attachment to the posterior papillary muscle. It is impossible to tell in the gross whether these are vegetations or former points of attachment of the ruptured cords. The posterior cusp also shows numerous nodular thickenings. Two hard, calcareous nodules, one nearly a centimeter in diameter, are felt in the substance of the cusp at its base. Over the larger of these at the point of junction of cusp and auricular wall is a small depressed area with rough surface. Over the other nodules the endocardium is smooth and glistening. The aortic cusps are normal—9 centimeters. Heart muscle appears normal. Right ventricular wall measures 2 centimeters. Coronaries normal.

Spleen: 255 grams. On surface are several patches of firmly adherent organized exudate. Capsule thickened. Very firm, deep red, trabeculæ prominent. Liver: Greenish yellow with thickly scattered deep red points ("nutmeg liver"). Gall-bladder: Contains large amount of very thick greenish red bile. Hepatic and common ducts admit passage of probe easily, and on dissection no calculi or other obstruction found. Pancreas: Normal. Kidneys: 195 grams. Capsules strip easily; tissue slightly yellowish and opaque; otherwise normal. Stomach and intestines: Normal. Bladder: Normal. Anatomical diagnosis: Chronic adhesive peritonitis; pericarditis; healed tuberculosis; double hydrothorax; thrombosis of branches of pulmonary artery; infarction of both lungs; cardiac hypertrophy; acute endocarditis; rupture of chordæ of anterior cusp of mitral; chronic passive congestion of liver and spleen. Bacteriological diagnosis: Culture from heart's blood; no growth. Microscopical diagnosis: Liver: Intense congestion about central veins with resulting atrophy of liver cells in center of acini. Many of liver cells about these areas filled with dark pigment. Pancreas: Slight increase of interstitial tissue. Kidneys: Capillaries congested; a few sclerosed glomeruli. Pulmonary artery: Branch shows occluding thrombus of fibrin, adherent to wall in places. Degenerated in center, undergoing organization at attachment to wall on one side. Another section shows occluding thrombus of large branch, extensively organized except in center, which consists largely of red blood capsules. Surrounding lung tissue infarcted. Lung: Area of infarction consists of extravasated blood and exfoliated cells of alveoli; over a large portion outlines of alveoli only roughly indicated by broken down connective tissue septa. Many of the exfoliated epithelial cells of the air vesicles are loaded with pigment. Two small vessels show partial obliteration of lumen by fibrin and red cells, partially organized. Heart: Muscle slight brown atrophy. Chordæ tendineæ show evidence of old chronic inflammation.

The case presented is of unusual interest on account of the rarity of the lesion, its mode of production, and the occurrence of a presystolic murmur in the absence of stenosis of the mitral valve. A review of the literature shows fifty reported cases, including eight ruptures of papillary muscles, a synopsis of which is appended to the present report. Many of them are old, some in the days before the use of refined methods of physical examination, and even that reported by so great a master as Laennec is difficult of analysis, owing to the incorrect views obtaining as to the production of the second heart tone, so that his statement that "the contraction of the auricle as long as that of the ventricle *donnait le bruit de soufflet*," leaves one in doubt as to his meaning. Presumably, as he regards the second sound of the heart as synchronous in time with auricular systole, the murmur heard was diastolic in time. As regards the cause of the rupture, the tendency of the early observers is to lay stress on physical effort and trauma, though if the cases be analyzed in many of them an endocarditis was obviously present, as proven by vegetation or valve change described in the autopsy reports. These changes were considered by some as secondary, but precisely on what ground it is difficult to see, except from the absence of symptoms prior to the trauma or strain.

On dividing the cases as reported it seemed wise to classify as follows:

1. Those cases due to severe traumata such as fractured ribs from violent compressions, falls from a considerable height, stab wounds, gunshot wounds; in one the kick of a horse. Of this group seven cases were found, resulting in four cases in a tearing of the papillary muscle rather than the chordæ themselves. The remaining three were due to stab and gunshot wounds and a fall from a window, respectively. That trauma of such severity in the region of the precordium could result in rupture of the chordæ will, I think, be admitted without comment.

2. Cases of ruptured chordæ in which the rupture

has followed efforts such as straining, lifting, excessive fatigue, and severe cough in which the autopsy disclosed no reported endocardial lesions in the heart. Of these five cases are reported, of which two showed blood vessel lesions, one an aortic aneurysm, and the other coronary sclerosis. Two cases also showed papillary muscle rupture, leaving only one case of actual chordæ rupture in hearts apparently free from any other lesion. This is the case of Dickinson. The patient, a young male, 21 years of age, had a severe pain under the left nipple while lifting a load of bricks, developed immediate signs of cardiac insufficiency, and died in two months. Autopsy carefully describes the valves as normal except for rupture of the chordæ attached to the posterior cusp of the mitral valve.

3. Cases of rupture said to be due to or preceded by strain, but in which endocardial or myocardial lesions were also found at autopsy. In this class nine cases are found.

4. Cases of rupture of the chordæ, in which endocarial lesion was found, but following no known history of strain or trauma. In this class are nineteen cases. Among these are a number in which no history was given or obtainable, these constituting a sub-class of mere pathological reports.

5. Reported cases of rupture in which data given are insufficient to determine the probable cause in which no autopsy has been made, and one ("Gilbin") whose report was not accessible. In this class are ten cases.

Obviously the cases with pathological change in the heart vastly outnumber the cases without, 28 to 12, and if we exclude the severe traumatic cases we reduce this latter group to 5, which may be still further reduced to 3 by excluding the 2 cases with vascular disease. Of the remainder 2 are ruptures of the papillary muscle, leaving but 1 pure tendon rupture. Overstrain alone would therefore seem to be an infrequent cause of this occurrence unless we regard the rupture itself capable of secondarily causing an endocarditis. This is the position of de Quervain, who reports a case of malignant endocarditis following a sudden muscular exertion. This contention he supports by quoting the production of endocardial lesion in animals by damaging the valves mechanically. Experimental evidence of the difficulty of rupturing the healthy chordæ is given by Barie, who, while able to produce aortic ruptures with pressures of 170 to 400 millimeters of mercury was able to produce rupture of the chordæ in only one case, and that at 1,085 millimeters of mercury, a pressure that is almost inconceivable in the ventricles and which apparently, under experimental conditions, is more liable to rupture the heart walls themselves than the chordæ. The ordinary pressure in the ventricle is but slightly higher than the pressure in the aorta, which may be taken roughly as its measure, maximal 3-400 millimeters. Libman reports in cases of subacute endocarditis such as are caused by his *Streptococcus viridans* the not infrequent localization of vegetations on the chordæ and occasional rupture, so that the number of ruptured chordæ may be greater than the reported cases indicate.

It seems fair to assume that the healthy chorda is rarely if ever ruptured by strain or exertion and that a preexistent endocarditis is necessary to rupture. That effort may rupture a diseased chorda is obvious. From the examination it is impossible in the reported case to state the date of the rupture of the chordæ. Probably, giving way one by one, the lesion dates from the onset of symptoms, the gradual increase in symptoms being due to the increasing insufficiency of his mitral valve. The symptoms of such a lesion are of course outspoken signs of mitral insufficiency with signs of cardiac insufficiency in proportion to the number of chordæ ruptured and the suddenness of the onset of leakage before the heart can accommodate itself. In a case where the patient is known to have had no cardiac signs, no enlargement of the heart, murmurs, or symptoms due to insufficiency, and where, following a straining effort in which the intraventricular pressure may be assumed to be greatly raised, a sudden severe pain is felt or a feeling as of something having given way, followed by severe dyspnea and signs of mitral leakage, a rupture of this sort may properly be suspected. On the other hand, when without history of strain a mitral leakage is found which gradually becomes worse owing perhaps to the consecutive giving way of the tendons, the lesion is indistinguishable from an ordinary mitral insufficiency, and this will be the case in the vast majority of such ruptures.

The origin of the presystolic murmur is less clear. Apart from complicating mitral stenosis or outspoken aortic insufficiency but three instances are reported of a murmur occurring in diastole. The doubtful case of Laennec previously alluded to makes a fourth. One of these, that of Barie, may be attributed to the perforation in the aortic valve producing a Flint murmur. The other two occurred in cases where the papillary muscle was torn off, leaving the flap with its tendons and muscles free to travel between auricle and ventricle respectively in systole and diastole. The murmur was described in one case as a systolic and diastolic murmur, in the other as a murmur in time presystolic, but not having a true presystolic character. "It was not soft nor was it a squeak." Our murmur was a fairly localized short murmur inside and above the apex, heard at times as far as the left sternal border and, though not intense, of a clearly rumbling crescendo character. As the anterior curtain of the mitral valve swung free it must have traveled from auricle to ventricle with each diastole, and the sound may conceivably have been due to the vibrations set up by the strong current of blood due to auricular systole. Much as a sail flaps in the wind when a fore and aft vessel comes about in a stiff breeze, so the increased strength of the blood current at this period of its cycle may have caused a murmur in the heart, due to vibrations of the free flap. A second possibility is that the abrupt termination of its course from auricle to ventricle brought it up with much the effect of cracking a whip.

SYNOPSIS OF PREVIOUSLY REPORTED CASES.

Portal: Observation concerning a case of rupture of two fleshy columns of the mitral valve. The lesion also involved the wall of the left ventricle.

Corvisart: Man 30 years of age, abuser of alcohol; transitory attacks of rheumatism; died soon after admission to hospital with symptoms of extreme dyspnea. Autopsy findings: Protuberant vegetations on margin of mitral valve and on semilunar aortic valves. The segment of the mitral valve in front of the aortic orifice was no longer attached by tendinous cords to the fleshy columns. The chordæ tendineæ were ruptured or detached, and it was barely possible to trace two of these cords at the level of one of the fleshy columns.

Corvisart also reports the case of a man 34 years of age who injured himself in trying to move unaided a barrel of alcohol; suffered from cough and palpitation of the heart; mitral valve studded with soft vegetations. In the examination of the pillars which support the mitral valve, two of them were seen to have been ruptured some time ago. The extremities of these two tendons were soft, smooth, and rounded at the site of rupture. It was not possible to locate on the border of the valve the exact spot where they must have been inserted before the rupture.

Corvisart reports a third case (Observation 40, page 263). The patient was a courier, 30 years of age, who was admitted to the hospital immediately after a horseback ride of one thousand miles, without any rest. He had crossed the Channel after this ride, and while at sea had felt a sudden great oppression, with hemoptysis. He died soon after admission, under symptoms leading, prior to the autopsy, to the diagnosis of an acute lesion of the heart, "undoubtedly a rupture of one of its parts." The left ventricle contained one of the large columns which support the mitral valves, floating free in the ventricular cavity. It had ruptured at its base, evidently quite recently, and a small clot was found near the site of the rupture.

Laennec: Man 35 years of age was admitted to the Neckar Hospital in Paris, with a history of heart trouble dating five months back. Thrill 5, 6, 7 spaces. The contraction of the auricle as long as that of the ventricle gave the bellows sound. Death soon after admission. Autopsy findings: The heart was enlarged, especially the left ventricle. One of the tendons which pass from the extremity of the columns to the free border of the mitral valve was ruptured towards its middle. The upper portion was smooth, and was folded under the mitral valve, but without adhesions. There were warty vegetations on mitral valve and left auricle.

Bertin: A consumptive girl, 22 years of age. A severe coughing fit led to rupture of one of the muscular columns in which the tendons of the tricuspid valve are inserted; at the autopsy this fleshy column was found to be broken, floating free in midst of the ventricular cavity.

R. Adams: Cheynes' case: A musician, 34 years of age, strong and well nourished, of irregular habits, was suddenly attacked with very severe pain in the left side of the chest, about the precordial region. The condition became steadily worse, with edema of the lower extremities, digestive disturbances, dyspnea, loss of strength, cerebral symptoms, and so forth. Death about two months after the onset of the symptoms. Autopsy findings: The most interesting feature consisted in the rupture of the chordæ tendineæ which attach the left auriculoventricular valve to the columnæ carneæ. This rupture concerned variable levels, four of these tendons being found floating by one of their extremities in the interior of the ventricular cavity. Excrescences on mitral and sigmoid valves.

Marat: A man, 44 years of age, laboriously rolling a very heavy barrel, suddenly felt something snap in his back, and was attacked by dyspnea and palpitation. Death, twenty months after the accident. Autopsy findings: One of the columnæ carneæ at which the tendinous cords of the mitral valve are inserted was entirely ruptured, and pulled out, as it were. The patient also had an aneurysm of the aorta; but he had never before complained of disturbances, which did not begin until the painful sensation referred to above.

Nicod: Autopsy findings, in case of a woman who had suffered from two attacks of suffocation, the last terminating in death: Rupture of two fleshy columns of the heart, at a distance from each other, of unequal length, with a different coloration of the ends.

Legendre: Autopsy findings in the case of a man who died under symptoms of dyspnea, soon after fracture of the ribs, from violent compression. On opening the left ventricle of the heart a large fleshy column, with tendons passing to the posterior segment of the mitral valve, was seen to be entirely broken and curled up on itself, entangled in two of its tendons.

Prescott Hewitt: A boy of 12 years fell from a height and died four hours after the accident. Autopsy findings: No external lesion on thoracic wall. Pericardium intact. Ecchymosis at point corresponding to upper portion of intraventricular septum; this bloody extravasate came from a small tear of the heart wall which extended to the upper portion of the septum and established a communication between the two ventricles. Two columnæ carneæ in the left ventricle were torn.

Williams: Policeman, age 27 years, habitual user of alcohol, lost flesh and strength for two years. Three months ago, on quickly mounting stairs, felt a very sharp pain in epigastrium; some days later, edema of lower limbs, dyspnea, etc. At time of admission, urine was scanty, blood-tinged, and slightly albuminous. Heart hypertrophied. Auscultation; systolic murmur loudest under left breast. Death a few days after admission. Autopsy findings: The two mitral cusps were found to be thickened and ossified, the chordæ tendineæ, inserted at the anterior valve, were ruptured at unequal heights, and the fragments were lined with soft vegetations. Posterior cusp was ossified, and its chordæ tendineæ were agglutinated.

Todd, R. B.: A man 31 years of age was admitted to the hospital with general edema, enlargement of the liver, marked dyspnea, and frequent cough. History of a stab wound three years previously in right side of chest, below nipple. Death ten days after admission to hospital. Systolic murmur apex and base. Autopsy findings: The valves were normal, with the exception of the tricuspid, which presented several interesting lesions. The anterior segment of the valve, namely that which separates the infundibulum from the auricular portion of the ventricle was suspended free in the ventricular cavity, retaining its connection with the heart only at the level of the fibrous auriculoventricular orifice. All the fibrous cords, inserted at the valve, were ruptured at different heights, leaving a fringed valvular border. The fleshy columns in which the cords originate were contracted and showed the rudiments of the broken chordæ tendineæ. The extremities of the latter presented small bulgings, similar to those seen at the end of the nerves in an amputation-stump.

Gordon: A woman 26 years of age admitted to the Whitworth Hospital with violent hemoptosis. The diagnosis of rupture of the chordæ tendineæ of the heart was rendered, on the basis of the sudden and violent pain in the region of the heart, followed by intense palpitation and weakness, as well as the decided character of the bruit, and *frémissement* at the root of the neck. She lived ten days after her admission and then sank. The immediate cause of death was pulmonary apoplexy. Examination showed very slight disease in the aortic valves, there was a slight deposit in the central valve. Sev-

eral of the chordæ tendineæ of the anterior portions of the mitral valve were ruptured, and covered with a soft, cheesy matter. There seemed to have been slight endocardial inflammation, followed by rupture of the chordæ tendineæ, and this, by the effusion of lymph, which lay in great quantities loose in the ventricle.

Allix: A prostitute, 25 years of age, was admitted to the St. Jean Hospital in Brussels, having become unconscious a few instants before during coitus. Patient complained of stifling; restless. Auscultation was impossible, heart sounds were confused and arrhythmic, but accompanied by a distinct vibratory thrill. Patient died one hour after admission. Thrill marked. Autopsy findings: Trace of an old endopericarditis, marked hypertrophy of the left ventricle. On opening the cavities it was seen that the chordæ tendineæ passing from the summit of the principal left columna carnea to the free border of the anterior segment of the mitral valve were ruptured in the middle; these tendons were very fragile and easily torn; their surface was found to present a large number of small round wart-like vegetations.

Lee, Charles A.: Man, aged 65 years, while driving a stake into the ground with a heavy piece of wood, felt something give way suddenly in the region of the heart, and immediately fell to the earth, gasping for breath, and laboring under excessive pain and dyspnea. He never was well again, but lived for about ten months afterwards, with increasing symptoms of heart disease. Autopsy: The endocardial membrane was much thickened from chronic inflammation, organized lymph was deposited beneath it. Several of the chordæ tendineæ of the mitral valve were ruptured, only their shriveled remains visible, while others, both of the tricuspid and mitral, were so contracted and adherent to each other as to contract the circumference of the valves to such an extent as almost to close their orifice, and of course to prevent entirely their healthy play.

Blakiston found the chordæ tendineæ shortened in 20 out of 46 cases of tricuspid regurgitation, in one of which he says: "One of the cords had apparently been broken, and was curled up into a nodule, like a pin's head."

Austin Flint: Woman 35 years of age, who had suffered for some years from heart disease. The interesting point connected with the specimen is not the contraction of the mitral orifice, which is common enough, but the presence of two vegetations of considerable size, one as large as a bean, the other somewhat smaller. The larger one is attached to the papillary muscle of the inferior curtain by what appears to be a small pedicle, which is a fractured extremity of one of the tendinous cords. The other concretion is upon another tendinous cord which has not been fractured.

Ransford E. van Gieson: Man aged 24 years was admitted to U. S. Naval Hospital, and presented hypertrophy of the heart, with tumultuous action, and a murmur with the first sound transmitted along the course of the aorta. Gradual aggravation, death about six months later. Autopsy findings in heart: On opening the left ventricle the aortic valves are found to be thickened, contracted and studded with tenacious fibrinous vegetations. The anterior portion of the mitral valve is also covered with similar vegetations. The chordæ tendineæ of the anterior portion of the mitral valve are all ruptured, shortened, and covered with tenacious fibrinous effusion. The free extremities which are expanded into small bean-shaped bodies when drawn with moderate force toward their original muscular attachment will not meet by a quarter of an inch. The chordæ tendineæ of the remaining portions of the mitral valve are healthy, presenting no traces of atheroma or ulceration.

Stokes, in his work "Diseases of the Heart and Aorta," details a case, extracted from the records of the Pathological Society, which in many respects is similar to the one observed by Van Gieson: "The cords of the anterior portion of the mitral valve were all broken across near to the fleshy columns; they were thickened, softened, and covered with beads of very soft lymph."

Pollock, J.: A woman, 42 years old, was admitted to King's College Hospital with severe pain, palpitation, dyspnea, and hemoptysis. Dr. Johnson diagnosed rupture of one or more of the chordæ tendineæ of the mitral valve. Post-mortem examination of heart: The pericardium contained four ounces of serum. The heart was large, the left ventricle being hypertrophied more than the right. One of the chordæ tendineæ of the mitral valve was ruptured. Mitral valve was diseased, and the orifice contracted. Aortic valves much thickened.

Kelly: Description of specimen derived from a woman aged 49 years. Symptoms of heart disease for about two months prior to death. Autopsy: Left ventricle, somewhat dilated, aortic valves healthy; slight atheroma of ascending aorta. The anterior curtain of the mitral valve was fringed on the auricular side with some fibrinous beads, and some were found on the tendinous cords also. The posterior curtain was found lying loose; all the chordæ tendineæ were ruptured, and many were much shorter than usual; some had a small bead of fibrin on their free extremity; all broke off close to a fibrinous deposit. It is probable that they were not all ruptured at once, as in some the fracture seemed quite smooth, while in others there was a little fibrin on the free extremity.

Dickinson: Patient, male, age 21 years. Perfectly well until four months previously, when he suddenly felt pain under left nipple while lifting heavy load of bricks. Unable to work since, became worse in hospital, and died after two months. Diagnosis of laceration of chordæ tendineæ in mitral valve was confirmed by autopsy findings. The chordæ tendineæ attached to the lower edge of the posterior flap of the mitral valve were all broken close to their insertion into the fleshy columns, excepting that one or two cords remained entire at one corner of the curtain. A solitary tendinous cord which was attached at the base of the flap near its center remained entire. The segment of the valve of which the cords had been broken appeared to have lost all valvular action, and must have swung uselessly from its base. The broken cords hung with loose ends, which had become somewhat thinned. The free edges of the mitral valve had become somewhat thickened and opaque.

Bristowe: Patient, man, age 62 years, died under symptoms of heart disease, which came on almost suddenly about three weeks before his admission to hospital. Autopsy findings: One of the tendinous cords attached to the posterior flap of the mitral valve was ruptured, the cord was much swollen, and of an opaque yellow tint; this change was most marked in the situation of the rupture. The lower portion of valve was dilated into a pouch and had a deep, rugged notch. Mitral was normal in all other respects. Aortic valve was perfectly healthy. Coronary arteries, calcareous.

Hanot: The patient, a man 37 years of age, was admitted with all the signs of mitral insufficiency; systolic murmur at apex, edema of lower limbs, enlarged liver, signs of bronchitis, etc. After three weeks' stay in the hospital he was suddenly attacked by oppression and breathlessness; the face was livid, the body covered with clammy sweat; irregular heart action, rapid death. Autopsy findings: Aorta, intact; valvular lesions of mitral valve; also three valvular tendons, about one centimeter long, whitish and thickened, were found to be ruptured and floating in the ventricular cavity.

Le Piez: A woman 24 years of age died suddenly, in syncope, no abnormal sounds in heart, on getting up out of bed, a fortnight after the onset of symptoms pointing to heart disease. At the autopsy the heart wall was found to be friable and in a state of fatty degeneration. One of the fleshy columns of the heart was ruptured, cut in two, at the junction of the two lower thirds and the upper third. The segment where the chordæ tendineæ are inserted was displayed between the two mitral valves. One rather large-sized tendinous cord was completely ruptured; it did not belong to the ruptured column.

Gilbin: Personal observation of a case of rupture of the tendons of the mitral valve. (Records not accessible).

Foot, A. W.: Man aged 23 years, who had died suddenly while in the act of getting into bed. (All the physical signs of regurgitation through the mitral valve had been present.) The cords, which were found broken across about the middle of their course, were two or three of those attached to the musculus papillaris, which regulates the larger curtain of the mitral valve, and were those nearest to that portion of the curtain which is adjacent to the interventricular symptom. The broken cords were studded with warty nodules of fibrin, both the ventricular and auricular surfaces of the principal curtain of the valve were covered with vegetations of a similar character, and continuous with those creeping along the chordæ tendineæ.

Willard Parker: The patient lived several years, suffering with heart disease. There were also fibrinous granulations upon the cords. This author also reports the following case: Sudden rupture of the chordæ tendineæ in a man occurring while running to a fire. Death occurred a few months afterwards.

Dalton, J. C.: Quotation of Dalton's case, September 14, 1859. A man aged 40 whose previous history was unknown, was found in his room comatose and died one hour later. Autopsy: The mitral valves were covered with several small vegetations. Two of the tendinous cords attached to the inner portion of the anterior curtain of the valve were ruptured. The rupture was at the point of attachment of the cords to the valve. The free ends of the cords were covered with fibrin, giving them a bulbous shape.

Alonzo Clark: There were vegetations on the broken ends of the cords, and upon the valves connected with them. There were vegetations on the cords of three or four other specimens which had been presented to the Society. In one case there was a thinning of the cords, ending in rupture; in other cases the cords were thickened, but softened. Chordal inflammation is apt to be followed by vegetations, softening, and rupture.

Metcalf, J. T.: Man, age 23 years, became rheumatic after an injury to the side and exposure to cold; developed dyspnea, edema of face, ascites, anasarca. Rough systolic murmur over mitral valves, effusion into pericardium and both pleuræ; albuminuria. Death from exhaustion. Autopsy: Several chordæ tendineæ were ruptured. The aortic valves were studded with fibrin, and insufficient; there was a large white clot in the heart.

Lionville: Case of an old woman, in whom the columns of the mitral valve were ruptured in consequence of a fall from a window on the third floor.

Terrillon: Man, age 48 years, gunshot wound of chest, penetrating the seventh rib; death twelve hours later. Autopsy showed extensive ecchymoses in the paricardium and myocardium of the anterior wall of the left ventricle; no solution of continuity; rupture of individual trabeculæ and mitral tendons.

Potain: Also quoted by Barié: A young woman died rapidly in the Pétié Hospital of Paris, with symptoms which were referred to puerperal endocarditis. At the autopsy all the tendinous cords of the flaps of the mitral valve were found to be ruptured, so as to produce a true acute insufficiency.

Barié: Woman, age 56 years; history of articular rheumatism, followed by symptoms of heart disease; mitral systolic murmur; thrill; death one week after admission to hospital. Autopsy: Heart not enlarged, cavities small, walls of left ventricle slightly thickened. The mitral valve was whitish and somewhat thickened; on testing with water, it was found that the posterior valve did not fit against the anterior valve, but floated in midst of the fluid, in consequence of rupture of four of its tendons. These tendons were broken about the level of their middle portion; they were somewhat thinned, but on examination presented no inflammatory changes. The aortic valves were normal. The tricuspid valve was intact and sufficient.

Potain: A man, 72 years of age, had died with symptoms of mitral insufficiency. The autopsy showed the presence of rupture of one of the tendons of the great mitral valve. The tendon had given way close to its insertion, and either floated in the ventricle or became interposed between the flaps of the valve, preventing their accurate junction, and giving rise to intermittent mitral insufficiency.

Sharples, C. W.: Laborer; systolic and presystolic murmur, latter not characteristic in quality. At the autopsy of a man 45 years of age there were found lesions of auricular endocarditis and a rupture of the chordæ tendineæ, which were changed in appearance and character, being all that were attached, most anteriorly and nearest the center of the valve, with only one remaining on the left, thus leaving the valve to flap back and forth without its normal control. The longest chordal fragment on the valve was three-fourths of an inch long. It was softened, thickened, and beaded, smooth over most of its length, with one hanging vegetation. Attached to another broken chorda was a mass half an inch long and one-eighth in diameter, fastened by a narrow, small, short pedicle. Otherwise it was free to flap about in the ventricle. The other chordæ presented no peculiarities, except that they were thick, soft, and very friable. One of the transverse bands connecting two chordæ near their origin presented a large vegetation.

Huchard, Degny: Man 42 years of age; mitral insufficiency, also aortic insufficiency. The tendinous cords inserted at the posterior pillar (angle of septum and ventricular wall) were adherent to the posterior commisure of the great mitral (cardioaortic)

valve. These parts were rigid and calcified, on one arterial surface. Analogous lesions were noted at the summit of the anterior pillar and the anterior commisure of the great mitral valve and the connecting chordæ tendineæ. But here the chordæ tendineæ were ruptured, one large tendon in particular being broken off about one centimeter from its insertion at the valve, so that this anterior portion of the great mitral valve, being free from all tendinous cords, had become displaced upwards, into the left auricle.

Hallé: In the case of a man 63 years of age, who had died from bronchopneumonia, after suffering for two months from symptoms of heart disease, the autopsy showed the rupture of several tendons and chordæ tendineæ on the left pillar of the mitral valve; two of these small tendons floated free in the auricle.

Poupon: A man 41 years of age had died from a ruptured gastric ulcer. The mitral valve was found to be insufficient and the seat of peculiar changes. A softened vegetation, probably a band attached to the lower border of the anterior pillar, floated free in the cavity, toward the cardiac apex, and therefore in the direction of the bloodstream. The flaps of the mitral valve were extremely thick and hard, with scattered calcified spots. The anterior pillars of the second class were connected by fibrous bands; one of these pillars presented an ulcer with calcified margins. All the constituents of the mitral valve and its pillars were considerably hypertrophied. The emboli found at the autopsy were attributed to the rupture of a tendinous band of a pillar of the mitral valve; the band itself was interpreted as the result of an old endocarditis. Murmur at apex. Time undetermined.

Henry: Rupture of the posterior papillary muscle, 2 cm. in length (one in thickness) of the mitral valve, in a young, robust male, known to be in good health two years previously. Death after about eight months, after transitory improvement following upon traumatism (a kick from a horse directly on precordium). The clinical picture showed a complicated recent cardiac affection, with the sole symptoms of disatolic-systolic murmurs and dilated heart (ox-heart), which were explained by the free floating papillary muscle; this hung suspended from the chordæ tendineæ, and was necessarily thrown constantly from the ventricle into the auricle, and back again through the bloodcurrent and the cardiac contractions.

De Quervain: Man, age 35 years, in good health, experienced a sudden painful sensation in the chest when holding up a very heavy barrel; this was followed by epistaxis and bloody expectoration. Later cyanosis, increased frequency of pulse-rate, and cardiac distress. No findings early on auscultation, but three weeks later a rough systolic murmur was heard at the mitral valve. The general condition became worse, and seven weeks after the accident the patient died under symptoms of cerebral embolism. Autopsy findings: Circumscribed thickenings at free margins of anterior mitral flap, 1½ cm. long, 1 cm. wide, irregular and friable. The valve in this area presented no chordæ tendineæ, but there was the stump of one. Microscopically the thickening was interpreted as a fresh endocarditis proliferation, in part ulcerative in character.

Schmidt: A man 85 years old fell out of the window from the second floor, landing on the left side of the thorax. Autopsy findings in heart: Posterior aortic valve presented a rupture through its entire thickness. There was also a tear 2 mm. long at the lower surface of the anterior mitral flap. The simultaneous rupture of the mitral valve is explained by the author in such a way that after the aortic rupture the sudden back-flow of the aortic blood struck the open mitral valve, thrusting it up, and partly tearing it away from its support, the chordæ tendineæ. The rupture had occurred immediately above the insertion of a tendinous cord of the second class, which is inserted at some distance from the free margin, on the surface of the valve. Otherwise the mitral valve and its tendinous cords, as well as the right-sided valves were unchanged. The heart was slightly atrophic; no degeneration of the myocardium.

Buchanan: Male. Symptoms cardiac insufficiency with fever four years before. Systolic murmur over cardiac area toward axilla and over vessels of neck. Autopsy: Mitral admits 3 fingers; anterior curtain presents an irregular fringe of ruptured chordæ, 8 in number. Free extremities bulbous and granular from endocardial thickening. One papillary muscle soft pale atrophied, is completely severed from tendon. A few vegetations on margin of curtain freed by rupture.

Hawthorne: Male gave up rowing 3 years before death on account of "weakness." No definite mitral insufficiency. Presystolic thrill and murmur at apex. Systolic over whole precordium. Autopsy: Mitral stenosis. Anterior flap projects into and half closes orifice. Three tendons are torn. Endothelium granular and swollen. Free edge of curtain studded with vegetations.

Barié: Case showing presystolic thrill and presystolic and systolic murmur at apex. Also diastolic at base. Autopsy: No mitral stenosis. Two chordæ of anterior valve ruptured, mitral calcareous. Hole in posterior cusp of the aortic valve.

Gordon: Rupture of the chordæ tendineæ. (Not accessible.)

Jayle: Systolic murmur at apex. Autopsy: Rupture of the tendon at anterior flap.

Norris: Signs of mitral disease following lifting effort. Examined before. No signs. After effort, systolic murmur at apex. Suspicion of presystolic. Diagnosis made of ruptured chorda. No autopsy.

For assistance in looking up the literature I wish to express my appreciation of the services of Dr. F. Robbins.

CAMPHOR AND PNEUMOCOCCI.*

By AUGUST SEIBERT, M.D.,

NEW YORK.

PROF. OF PEDIATRICS, NEW YORK POLYCLINIC; ATTENDING PHYSICIAN, ST. FRANCIS HOSPITAL.

Since the publication of my first report on the action of large doses of 20 per cent. camphorated oil injected hypodermically in pneumococcic pneumonia (*Münch. med. Wochenschrift*, No. 36, 1909), some further observations have been made which are of sufficient importance to warrant publication.

The blood culture work of the last decade has shown (1) that the pneumococci enter the blood (in pneumonia) at the time of the initial chill, in fact, cause it; (2) that they remain there till after the crisis, and (3) that they there cause the toxemia, the life danger, and, in fatal cases, the death of the patient. Therefore a successful treatment of the pneumonic must consist in either binding the toxin by a serum or in destroying the vitality of these organisms, directly or indirectly, by chemotherapy.

Roemer's antipneumococcic serum, introduced ten years ago (*von Graefes' Archiv*, Heft, 54, 1902), has since been tried extensively in Germany. The reports of twelve clinics up to the close of last year are conflicting. Following the suggestion of Neufeld und Handel ("Arbeiten aus dem Kaiserlichen Reichsgesundheitsamt," vol. 34) Beltz gave 400 units in twenty-two cases intravenously every twenty-four hours in the Augusta Hospital in Cologne (*Deutsch. med. Woch.*, No. 1, 1912), with the result that ten patients recovered within four days by crisis.

The first attempt to reduce the vitality of pneumococci in the blood of a patient by introducing large doses of camphor was made by the author in September of 1906, in the case of a young woman brought to St. Francis' Hospital on the third day after the initial chill with the symptoms of severe toxemia (unconscious, temperature 105.5° F., pulse 130, and respiration 40) and involvement of both lower lobes. An extended experience (since 1889) with the action of large doses of camphoric acid in influenzal infections suggested the use of large doses of camphor in this desperate case, and so 12 c.c. (instead of 1 or 2 c.c. used till then for stimulating purposes) of the 20 per cent. camphorated oil were injected hypodermically every twelve hours, resulting in *gradual* improvement and recovery by the fourth day, without a crisis. Only the alveolar exudate in the lung did not disappear until the tenth day after the chill.

In the following twenty cases of pneumococcic pneumonia these camphor injections invariably reduced the toxemia gradually until practically normal conditions were reached three or four days after the first injection, while the alveolar exudate remained, to be absorbed later on. This phenomenon and the *absence of a crisis* were noticed in every case.

In these twenty-one cases (reported on in my first paper) 12 c.c. of a 20 per cent. camphorated oil were injected every twelve hours in adults, and 6 c.c. in children (the youngest being four years of age), irrespective of the size and weight of the patient, the intensity of the toxemia, and the extent of the local process.

In four of the next sixteen cases the limitations of this treatment were observed. A sudden rise of temperature in two patients on the second and third days of treatment, respectively, proved to be due to pneumococcic nephritis, promptly subdued by appropriate doses of urotropin, while the camphor injections were continued and resulting in speedy recovery.

In two cases of severe pleuropneumonia from the onset (aged thirteen and twenty-eight respectively) the camphor reduced the general toxemia markedly, but did not prevent the accumulation of pus in the pleura, necessitating rib resection in the one on the fourth, and in the other on the eighth day after the initial chill, pneumococci in pure culture being found in the exudate, and both patients recovering.

This proves that the camphor brought into the blood cannot prevent the as yet living organisms, constantly entering the blood current from the affected alveoli, from colonizing in the renal and pleural tissue. Considering the fact that the camphor but gradually reduces the vitality of the pneumococci, nothing else could be expected, no more than that the very small amount of camphor, reaching these bacteria already established in the kidney or pleura, could inhibit a pneumococcic nephritis or pleuritis.

The one death among the thirty-seven cases of pneumonia so treated occurred in a man 68 years of

*Read at the meeting of the Medical Society of the County of New York, March 25, 1912.

age, weighing 200 pounds, with fatty heart, attacked by pneumococcic invasion of both lower lobes, marked toxemia, and copious bloody sputum. Although early camphor injections had the usual good effect on the sensorium, the temperature, and the respiration, his flabby heart began to give out on the fifth day, resulting in fatal pulmonary edema on the sixth.

This experience caused the author to consider the possibility of (1) increasing the strength of the camphor oil, and (2) the addition of some other chemical with the object of insuring a prompter action.

The next few patients were given 10 c.c. of a 30 per cent. camphor solution in sesame oil to every 100 pounds of body weight every twelve hours in unilateral pneumonia with average toxemia, and every eight hours in bilateral involvement with a severe toxemia. This plan proved effective in so far as to decrease the temperature, pulse, and respirations more markedly, but nevertheless requiring at least three days to practically reach normal conditions.

The pneumococcus is a unique parasite, on account of its capsule, through which the endotoxin enters the blood of the patient. If a more aggressive chemical, added to the oil, could cooperate with the camphor, not alone the blood serum might be changed to an unsuitable culture medium (as is done no doubt by the camphor) but also the organisms could possibly be damaged directly by destroying their capsules.

During the last four years I had made many hypodermic injections of 10 per cent. salicylic acid solutions in 20 per cent. camphor oil in rheumatics, and had observed the prompt destruction of meningococci in the blood of a two-year-old patient by a 3 per cent. salicylic acid solution in a 30 per cent. camphor oil, 5 c.c. being injected every forty-eight hours.

Three years ago Dr. Hensel, assistant pathologist at the German Hospital, in a series of experiments made at my request, found that 1 to 10,000 part of camphor added to the usual culture media inhibited the growth of pneumococci, while the controls all thrived. At the same time Dr. J. C. Welch, pathologist of the Lying-in Hospital, found that 1 c.c. of 20 per cent. camphorated oil, given hypodermically in rabbits and repeated every twelve hours after a fatal dose of pneumococcus emulsion had been injected intravenously, inhibited the fatal outcome, but one animal succumbed out of six. (Reported in my first paper.)

To test the action of the 30 per cent. camphorated oil against pneumococcic toxemia in rabbits, and to compare this with the action of the same oil to which salicylic acid had been added, Dr. G. A. Rueck, assistant pathologist of St. Francis' Hospital, at the request of the author, made twenty-seven experiments, of which the last twenty shall be mentioned here, as the others were of a preparatory nature.

Rueck first injected 2¾ c.c. of a pure culture of pneumococcic emulsion intravenously into a rabbit weighing 2,325 grams, the animal dying promptly after 36 hours. From the heart blood the organism was isolated and used for the following experiments to insure sufficient virulence:

One c.c. of a 24 hours' broth culture of pneumococci introduced intravenously in a rabbit weighing 1,500 grams proves fatal in from 24 to 36 hours, according to numerous experiments. But in the first 8 experiments of Rueck 1½ c.c. of this culture was injected intravenously, irrespective of the weight of the animals, 6 hours before the camphor oil, with or without an addition of from 1 per cent. to 3 per cent. of salicylic acid, was given hypodermically in doses of 2 to 5 c.c., and repeated every 12 hours, with the result that the animals weighing but 1,000, 1,065, and 1,165 grams respectively, died within 48 hours; two others weighing 1,345 and 1,445 grams respectively, but having been given

TABLE No. 1.

EXPERIMENTS WITH THREE FATAL DOSES OF PNEUMOCOCCI.

Weight of Animal	Amount of Inoculation	Time of Inoculation	Time of First Camphor Injection	Quantity of Oil Injected Every Twelve Hours	Temperature of Animal Before and After Inoculation	Result
1000 G.	1½ c.c.	4 P.M.	10 P.M.	4 c.c. of 30 per cent. Camphor Oil + 2 per cent. Salicyl. Acid,	102° 106° F.	+ in 28 hours
1065 G.	1½ c.c.	4 P.M.	10 P.M.	3 c.c. of 30 per cent. Camphor Oil + 2 per cent. Salicyl. Acid,	103° 105.8° F.	+ in 24 hours
1165 G.	1½ c.c.	4.15 P.M.	10.15 P.M.	5 c.c. of 30 per cent. Camphor Oil	101.4° 104.6° F.	+ in 30 hours
1325 G.	1½ c.c.	4.30 P.M.	10.30 P.M.	5 c.c. of 30 per cent. Camphor Oil	101.4° 104.6° F.	Recov'd in 4 days
1345 G.	1½ c.c.	4.45 P.M.	10.45 P.M.	2 c.c. of 30 per cent. Camphor Oil + 1 per cent. Salicyl. Acid	102° 101.2° F.	+ after 4 days.
1445 G.	1½ c.c.	5 P.M.	11 P.M.	2 c.c. of 30 per cent. Camphor Oil + 2 per cent. Salicyl. Acid	102.2°—106.8° F.	+ after 5 days

2030 G.	1½ c.c.	5.30 P.M.	11.30 P.M.	3 c.c. of 30 per cent. Camphor Oil + 3 per cent. Sacliyl Acid	101° 104.6° F.	Recov'd in 3 days
2175 G.	1½ c.c.	3 P.M.	9 P.M.	5 c.c. of 30 per cent. Camphor Oil	103.8° 106.8° F.	+ in 5 days.
1275 G.	1 c.c.	3.15 P.M.	9.15 P.M.	5 c.c. of 20 per cent. Camphor Oil	102.8° 105.2° F.	+ in 4 days

TABLE No. 2.

EXPERIMENTS WITH FATAL DOSES OF PNEUMOCOCCI.

Weight of Animal in Grams	Amount of Inoculation	Time of Inoculation	Time of First Camphor Injection	Quantity of Oil Injected Every Twelve Hours.	Temperature of Animal Before and After Inoculation	Result
1000	¾ c.c.	3 P.M.	9 P.M.	5 c.c. of 30 per cent. Camphor Oil	103.2° 105.6° F.	Recov'd in 4 days.
1160	¼ c.c.	3.15 P.M.	9.15 P.M.	4 c.c. of 30 per cent. Camphor Oil + 1 per cent. Salicyl. Acid	103.6° 105.2° F.	+ in 4 days.
1335	1 c.c.	3.30 P.M.	9.30 P.M.	4 c.c. of 30 per cent. Camphor Oil + 1 per cent. Salicyl. Acid	103.6° 105.4° F.	+ in 4 days.
1425	1 c.c.	3.45 P.M.	9.45 P.M.	5 c.c. of 30 per cent. Camphor Oil	102.8° 105.6° F.	+ in 4 days
1455	1 c.c.	4 P.M.	10 P.M.	3 c.c. of 30 per cent. Camphor Oil + 1 per cent. Salicyl. Acid	101.2° 106.2° F.	Recov'd in 4 days.
1455	1 c.c.	4.15 P.M.	10.15 P.M.	5 c.c. of 30 per cent. Camphor Oil	102.2° 106.2° F.	Recov'd in 5 days.
1600	1 c.c.	4.30 P.M.	10.30 P.M.	5 c.c. of 30 per cent. Camphor Oil	103.8° 105.6° F.	+ in 3 days.
1600	1 c.c.	3 P.M.	9 P.M.	3 c.c. of 30 per cent. Camphor Oil + 1 per cent. Salicyl. Acid.	101.2° 106.8° F.	Recov'd in 4 days.
2025	1½ c.c.	3.15 P.M.	9.15 P.M.	5 c.c. of 30 per cent. Camphor Oil + 1 per cent. Salicyl. Acid	103.6° 106.2° F.	Recovered in 5 days.
2050	1½ c.c.	3.30 P.M.	9.30 P.M.	5 c.c. of 30 per cent. Camphor Oil	102.6° 105.8° F.	Recovered in 4 days

but 2 c.c. of salicylated camphor oil, lived 3 and 4 days respectively, and that the remaining three animals weighing 1,325, 1,635, and 2,030 grams respectively, the first treated by 5 c.c. of the 30 per cent. camphor oil, the second with the same plus 2 per cent. salicylic acid, and the third with 3 c.c. of the 30 per cent. camphor oil plus 3 per cent. salicylic acid, recovered within 5 days.

That the first 3 undersized animals were killed by the amount of toxin which had formed in the 24 hours' broth of this overmortal dose was evident from the low temperatures found in the rectum of these rabbits on the day after inoculation (98°, 90.4°, and 101.4°).

The next two animals, weighing under 1,500 grams, responded to this overdose of pneumococcic broth by rectal temperatures of 106.6° and 107.4° F. respectively, and being treated by but 2 c.c. of 1 per cent. and 2 per cent. salicylated camphor oil, lived 5 days, 3 days longer than if they had not so been treated.

The 3 remaining animals survived this overdose of pneumococcic broth (1) on account of their size (weighing 1,325, 1,635, and 2,030 grams respectively), and (2) because the first was treated by 5 c.c. of the 30 per cent. camphorated oil, the second by the same dose plus a 2 per cent. addition of salicylic acid, and the third by 3 c.c. of this oil with a 3 per cent. salicylic acid addition.

In the second series of 12 experiments the amount of pneumococcus emulsion was graded to the rule of 1 c.c. to 1,500 grams of animal weight, but the amount of camphor oil injected was not graded, varying between 3 c.c. and 5 c.c. per dose.

Of these 12 animals 6 recovered within 4 to 5 days, 3 of the 7 treated by pure camphor oil, and 3 of the 5 treated by the same oil plus 1 per cent. salicylic acid. Of the 6 animals which died 1 lived 3, 4 lived 4, and 1 lived 5 days after the inoculation. The rectal temperatures of the animals were taken daily at 8, 12 and 6 o'clock, before and after inoculation.

In looking over Rueck's report on his last 12 experiments the author finds that of the 6 animals which succumbed in his experiments 3 rabbits weighing but 1,425, 1,335, and 1,275 grams respectively had been given the full fatal dose of pneumococcic broth for an animal weighing 1,500 grams. The immunizing ability of 75, 165, and 225 grams of body tissue deducted from an animal of 1,500 grams body weight is no trifling matter in pneumococcic infection.

Again, a fourth animal weighing 2,135 grams was inoculated with 1 1/3 c.c. of the virulent pneumococcic broth culture, a fatal dose for a rabbit of 2,840 grams. 705 grams of body tissue deducted from 2,840 grams of body weight may change the ultimate result in an experiment. These figures prove that Dr. Rueck, who was given a free hand in these experiments, made no efforts to produce favorable results of the camphor treatment in pneumococcic toxemia.

It also must be kept in mind that in injecting pneumococcic broth into the blood current an unknown quantity of toxin is introduced with the organisms, the action of which may decide the issue.

Many parasites produce more toxin than few. The question of quantity is of importance not alone in judging the severity of an infection but also in determining the amount of the curative drug.

Summing up we find that in 17 out of 20 animals inoculated with the fatal dose of pneumococci, death was retarded from 2 to 5 days by camphor oil injections in 8, and entirely prevented in 9.

As the first three animals were given at least twice the fatal amount of pneumococcic broth that in all reason they should have received, it is but fair, in estimating the action of the camphor treatment, to leave their career out of account.

Comparing the results of Morgenroth and Levy in the Pathological University Institute in Berlin (*Berlin. klin. Woch.*, Oct. 30, 1911), who injected the fatal pneumococcic dose into the peritoneum of mice, and 5 to 6 hours later 0.75 c.c. of 0.75 per cent solution of aethylhydrocuprein (an alkaloid of the quinine group) and saved 12 out of 22 animals, Dr. Rueck can be satisfied when considering that in his experiments the fatal dose of pneumococci was in the blood current from the start.

These attempts to interfere in human and animal pneumococcic infections with camphor have established the following facts: (1) That 10 c.c. of a 30 per cent. camphorated oil (equal to 36 grains of pure camphor) injected hypodermically to 100 pounds of human body weight every 8 to 12 hours, do not produce symptoms of poisoning, in fact are harmless; (2) that much larger doses (to the body weight) in rabbits are equally well borne, and (3) that *these quantities of camphor materially assist in overcoming pneumococcic toxemia;* and (4) that the earlier this treatment is resorted to the better the results.

Want of material has so far prevented me from comparing the action of the 1 per cent. salicylated with that of the pure 30 per cent. camphorated oil in pneumonia sufficiently to venture a conclusion.

The injections are best made along the outer thigh. A Luer syringe of 10 or 20 c.c. capacity (without rubber washer) must be used. The oil must be sterilized in a large-mouthed bottle with the loosely fitting stopper in a boiling waterbath, and drawn from it (not poured) into the sterilized syringe.

The point of injection is best rendered sterile by a few drops of the tincture of iodine. While injecting, the skin with the subcutaneous fat must be well drawn up, so as to deposit the oil below (not into) it.

In fat patients it is practical to inject the requisite quantity in two localities. In lean persons 20 c.c. can be deposited without discomfort.

Abscesses are due to faulty sterilization, and sloughing of the skin to faulty technique.

114 East Fifty-seventh Street.

GERIATRICS.*

By I. L. NASCHER, M. D.,

NEW YORK.

SPECIAL LECTURER IN GERIATRICS, FORDHAM UNIVERSITY SCHOOL OF MEDICINE.

The branch of medicine for which I suggested the term "geriatrics" is neither a fad, a hobby, nor a recent innovation in medicine. As a philosophical study senility engaged the minds of Cicero and Seneca. Senile diseases are mentioned in the works of Hippocrates and Galen. The alchemists of the middle ages studied the senile organism and the senile changes and made their panaceas to prevent those changes, for according to the second of the three articles of faith laid down by Jaffir El Gebbir, there existed a red elixir which would cure diseases, re-

*Read before the Medical Society of the County of New York, March 25, 1912.

juvenate the aged, and prolong life. Bacon and Descartes wrote treatises on old age. The best known of recent philosophical writings are those of Jean Finot and Metchnikoff, although the works of the latter are really philosophical deductions from scientific research. The earliest medical work dealing specifically with the diseases of old age is Floyer's "Medicina Gerocomica," published in London in 1724. There are several other works of the eighteenth century dealing with this subject, but the earliest work to leave any marked impress upon the medical profession was Canstatt's "Krankheiten des höherem Alters und ihre Heilung" (Diseases of Advanced Age and Their Cure), which appeared in Erlangen in 1839. While this is the first of the scientific treatises on diseases of old age the ground had been well prepared by earlier writers. In Bichat's work, "La Vie et la Mort" (Life and Death), which appeared in 1800, there is a description of the physiological changes that go on in the process of aging. Cruveilhier's monumental work on pathological anatomy contains descriptions of the pathological changes that are found in diseases of the aged. Pinel in his lectures delivered more than a century ago in the Salpetrière, the home for aged women in Paris, and later in his work on clinical medicine, described diseases of the aged. Landre-Beauvais, Rostan, Hourmann, and Dechambre, all prepared the ground for Canstatt and for Prus, who in 1840 presented to the French Academy of Medicine a monograph entitled "Recherches sur des Maladies des Vieillards" (Researches into Diseases of the Aged). Since then the principal French writers on this subject were Beau, Gillette, Durand-Fardel, Brown-Sequard, Charcot, Demange, Rauzier, whose "Traité des Maladies des Vieillards" (Treatise on Diseases of the Aged) appeared in 1909, and Pic, whose work, "Précis des Maladies des Vieillards" (Summary of the Diseases of the Aged), appeared a few months ago. The principal German writers since Canstatt were Geist, Mettenheimer, Friedmann, and the latest, Schwalbe, whose "Lehrbuch der Greisenkrankheiten" (Textbook on Senile Diseases) appeared in 1909. Schwalbe had the collaboration of many of the most eminent men of Germany, men like Ewald, Naunyn, Grawitz, Hoppe-Seyler, Hirsch, Oertner, Siemerling, Sternberg of Vienna and men of like caliber. Schwalbe's work contains references to 446 authors, of whom 68 are French, 24 are English, 8 are Italian, and but 6 are American, and 3 of these 6 are really German physicians. The paucity of American literature on this subject is more forcibly brought out by the fact that there is not a single work on senile diseases by an American writer except what can be found in journal literature. In 1881 a work, "Diseases of Old Age," by Charcot and Loomis, appeared in Wood's Medical Library, but that was merely a translation of Charcot's work which first appeared in 1869, to which were added a few lectures by A. L. Loomis, and in 1890 in one of Wood's monthly monographs there appeared a lengthy article by Seidel of Berlin.

The cause for the general neglect of this subject in this country is readily explained. Here the desirability of men and things is gauged by their practical value. The senile are economically worthless, their idiosyncrasies rob them of sympathy, their unesthetic appearance robs them of interest. The physician dealing with them realizes the hopelessness of ultimate success, and where failure is a foregone conclusion it is not in human nature to exert oneself to the utmost even if there is a possibility of temporary improvement. Under such conditions the physician will prefer to devote his time and energies in a more fruitful field. But the medical profession has as its fundamental principles, sympathy and science; sympathy to relieve distress wherever it may appear, science to study life and how to prolong it, and in no other branch of medicine can these be carried out to the same extent as in geriatrics. I need not speak of the humanitarian aspect of geriatrics. From the scientific standpoint there is no branch presenting problems more interesting, possibly of more profound import, than this. Take the basic problem why do we age. May there not be some controllable factors underlying the senile processes? There is undoubtedly a determining factor, perhaps an inherent property in all living matter which limits its growth and causes the senile processes which end in death. It may be a series of evolutionary changes in the cells such as I described in a paper on tissue cell evolution as a theory of senescence. There are contributing factors which retard or hasten the senile changes, as the senile stoop with its consequent compression of the lung and impaired hemic aeration, more pronounced in those accustomed to slouch than in those accustomed to an erect bearing, and in women who never wore corsets than in those accustomed to stays. Pneumokoniosis is rarely found in old sailors, but is rarely absent in old city dwellers. May we not find among these contributing factors some which are controllable and through the control of which we may be able to defer or retard the senile processes which we call degenerative, though they be the normal physiological processes of advanced life? Is it not possible to stimulate the aged organs and tissues to the extent that mental and physical activity are temporarily restored, thereby producing a true though momentary rejuvenescence? I have worked for some years upon this problem, but the results have not been brilliant; they have been mostly failures. Still, it has been possible in a few cases to so stimulate mental and physical energy and vigor as to restore temporarily the working capacity and the economic usefulness of the individual. I believe more extensive research with this end in view will bring to light measures or methods by which we shall be able to increase the waning powers of the aged individual and thus bring about a true though temporary functional rejuvenescence. In the paper of Seidel to which I have referred he says: "Mistakes are made daily in the treatment of the aged, and the normal mortality of advanced life is considerably increased as a consequence of the hitherto neglected study of the anatomical and physiological peculiarities of the senile organism." That holds as good to-day as when it was written twenty years ago.

To this ignorance of the senile state I will add a universal error, a wrong conception of disease in old age. The senile degenerations are natural, normal, and physiological at that period of life. Occurring at an earlier period they are unnatural, abnormal, and pathological. If we take a hale, hearty man of seventy we will find a number of degenerative changes, yet the degenerated organs functionate harmoniously and give no manifestations of disorder. The functions are performed less actively than in maturity, the secretions and excretions are diminished, the circulation is weaker, respiratory capacity and activity are lessened, there is less physical power, nerve responses are slower, the mental

powers are deteriorated, and the whole organism is depressed. In comparison with the healthy individual in maturity every organ and tissue is diseased, but if we look upon senility as the pediatrist looks upon childhood, as a physiological entity entirely apart from maturity, we must consider this old man in perfect health. Taking this view, disease in old age is not a perversion of function or growth from the norm of maturity, but from the norm of senility. The senile form of arteriosclerosis, if not excessive, is natural and normal, and nothing we may do can make it more normal or lessen it. We may be able to relieve disagreeable symptoms, but we cannot improve the condition. If under treatment there is an improvement then we have had a pathological condition due to a disease cause and what remains after the limit of improvement has been reached is the normal senile arteriosclerosis. If we accept the view that senility is a physiological entity like childhood, we will get a new conception of the diseases of old age. We will then consider the so-called diseases of metabolism which prevail almost exclusively in advanced life, as diabetes, gout, chronic rheumatism, postclimacteric obesity, and the diseases which occur in the aged alone, as paralysis agitans and atrophic emphysema, as perversions in the process of senile involution; and the perversions in cell growth, as in hypertrophied prostate and perhaps in carcinoma, will fall under the same head. The pathogenesis of such diseases might be explained by the theory of tissue cell evolution, but I have not had the opportunity to verify this theory.

Ignorance of the anatomical and physiological peculiarities of the senile organism gives rise to errors in diagnosis through faulty observation, faulty interpretation, and faulty deduction from senile manifestations. Cases present manifestations of senility which simulate diseases, as the contracted liver, which may be mistaken for cirrhosis of the liver. Sometimes the manifestations of normal senile changes are so pronounced as to mask the symptoms of a grave disease as when the senile emphysema masks the symptoms of a senile pneumonia. The symptoms of a grave disease may be so obscure as to be unnoticed or uninterpretable and this frequently happens in cases where death resulted without clearly defined symptoms. We say death from old age, but in most of these cases a post-mortem examination reveals a pulmonary congestion and edema. Pathologists frequently report the finding of chronic interstitial nephritis at autopsies of aged persons who gave no evidence of this condition during life. It is probable that in these cases the pathologist fails to distinguish between the kidney of chronic interstitial nephritis and the normal senile contracted kidney which shows the histological change first described by Jos. P. Walsh, of Philadelphia: a gradual progressive increase in connective-tissue growth between the aspices of the pyramids which goes on from birth. Complications that are rare and generally curable in maturity are frequent in senility, and unless dealt with in time they are often fatal. In many senile cases we find a number of symptoms which appearing in maturity form a pathognomonic symptom complex. In senility if each symptom is traced to its source we will find an entirely different condition from that which the symptom complex would indicate. The senile climacteric has as one of its most marked manifestations a pronounced change in mentality and lack of recognition of this transitional period between old age and senility, a period lasting several months, leads to errors from which may arise grave judicial wrongs.

In a paper so general in its scope as this little attention can be given to detail, yet I will mention a few diagnostic points in senile cases. Mouth temperature may be two degrees or more lower than rectal temperature. A temperature of 103° or more indicates a grave, probably acute inflammatory, disease, but such a disease may be present with little or no elevation of temperature. Atrophic emphysema and aortic regurgitation are present in almost every senile case and we must disregard these symptoms when examining the chest. Radial arteriosclerosis is usually more pronounced on the right side. The difference between the two sides makes the pulse and radial blood pressure misleading. Aches and pains often diagnosed as rheumatism are generally due to the senile hardening of cartilages and tendons and stiffening of joints and will not respond to medical treatment. Diseases usually painful in maturity as the serous inflammations, gout, pneumonia, etc., may be present in the aged yet produce little distress. Neither pulse, pain, nor temperature is of much service in determining the diagnosis, the personal history as given by the patient is often unreliable, and unconscious mimicry often gives rise to symptoms for which no pathological condition can be found.

Faulty diagnosis naturally gives rise to faulty treatment, but even when a correct diagnosis is made the aged are frequently improperly treated through our ignorance of the action of drugs and other therapeutic agents upon the senile organism. Assimilation is slow, cumulative action is frequent, and the secondary action of drugs is often more pronounced than the primary effect. The danger from the opiates lies in the secondary effects upon the respiratory centers. In the popular aloin, strychnine, and belladonna pill the action of the belladonna which inhibits peristaltic activity destroys the desired action of the aloin which is a peristaltic stimulant. The only rule for dosage in old age that we now have is the ancient dogma that children and the aged cannot stand large doses and doses are reduced without rule or system. Ask yourselves if you have any other rule for diminishing doses in old age than a rough guess. Yet in a great majority of senile cases, and with most drugs, doses must be increased. Take senile constipation for example. This is due to atony and waste of the muscular fibers of the intestines, and the remedy is peristaltic stimulants. In the beginning small doses may suffice, but as the atony and waste proceed larger doses will be required, and if we change the drug the new drug must be given in correspondingly large doses. The rule for dosage in old age is to increase the dose of stimulants and diminish the doses of depressants, beginning with the average dose of maturity and adding correctives to counteract secondary effects of depressants. At the same time we must remember that excessive stimulation of an organ increasing its activity, increases its waste, and hastens its degeneration. For this reason we must save the organs when possible, supplying secretions instead of forcing the secreting organs to increased activity, supplying for example the bile salts instead of using hepatic stimulants. Lessen the work of the lungs by supplying the denser and clearer atmosphere of the seashore. Lessen the work of the heart by rest and freedom from excitement. Lessen the work of the brain by removing sources of worry, irritation, and mental activity. In maturity nature cures, in

senility nature kills. A perversion of function or anatomical relation in maturity has a tendency to return to the norm of health if the cause is removed. In senility a pathological state of an organ hastens the degeneration of that organ, and if left to itself it will cause death. Active measures must be taken even in slight ailments, for they will involve allied organs which cannot accommodate themselves to functional derangement in another organ owing to their own degenerated condition. The neglect of these minor ailments, which are generally dismissed with the verdict "old age" is responsible for many deaths which might have been prevented if a more sensible diagnosis had been made and acted upon. The physician's verdict of old age is now virtually a death sentence when it might in many cases hold out some hope for prolonged life and continued usefulness.

The home care and institutional care of the aged have received little attention, yet they involve problems affecting the health and comfort of the aged individuals. So simple a thing as the shape of the chair has an influence upon the person's welfare. Seated in an ordinary chair the hands fall into the lap and the upper part of the chest is slightly compressed. Seated in an arm chair with the arms upon the rests, the upper part of the chest is slightly expanded without effort. This may appear insignificant in maturity, but in senility anything which will tend to aid in the expansion of the chest without increased physical effort is beneficial. There are many other similar apparently insignificant factors which are ignored in the care of the aged. The recreations, diet, clothes, sleep, should all be considered when dealing with this class of cases. Of the greatest importance is the early observation and interpretation of deviations from the accustomed routine of life, and especially of such symptoms as lassitude, headache, constipation, urinary difficulties, loss of appetite, and dyspnea. Mumbling during sleep may be a low muttering delirium and the family's diagnosis of failing rapidly is often the rapid exhaustion which accompanies senile pneumonia. Time does not permit me to go further into my subject. I have touched upon but few of the many factors which must be considered when dealing with the aged. I have merely scratched the surface, yet I hope that I have uncovered some things new to you in the realm of medicine. It is a source of gratification that one medical school has considered geriatrics, this neglected branch of medicine, of sufficient importance to include it in its curriculum.* I will be well satisfied if I have been able to impress the reader with its importance and to arouse in him an interest in the aged that he may apply to them those noble principles of our profession, sympathy and science, sympathy to relieve them of their ailments, science to study and prolong their lives.

*Since this was written I have received an invitation to deliver a course of lectures on Geriatrics at the College of Physicians and Surgeons of Boston and also at the Bennett Medical College, Chicago.

Neuroses and Gynecological Affections.—Lanfrognini describes various hysterical manifestations associated with gynecological disorders, especially inflammatory ovarian troubles occurring during the puerperal state and congenital alterations in the form and position of the uterus. The treatment of these lesions with a view of re-establishing the uteroovarian functions had an excellent effect on the nervous phenomena. Aside from the reflex effect of these lesions it is believed that the perversions of ovarian function are probably accompanied by a general autointoxication due to perverted internal secretions.—*La Riforma Medica.*

FREE POSTGRADUATE MEDICAL INSTRUCTION.

BY GEORGE MANNHEIMER, M.D.,

NEW YORK.

THE subject of postgraduate medical education formed an important topic in the general session of the last International Medical Congress, held at Budapest in 1909, and the following resolutions formulated by Professor R. Kutner, of Berlin, were adopted:

"A medical education should not be considered finished at the end of the university course. The constant progress of science requires of the physician an equally unremitting effort in the direction of further study. Physicians must be given opportunities to supplement their knowledge without great material sacrifice on their part. These opportunities must be offered the physician free of expense, and, furthermore, at time and place most convenient to him. In all large cities there should be created educational centers for which the local hospitals could be utilized and in which physicians capable of teaching may act as instructors. While at present lectures and courses given in scientific institutions and hospitals must be accepted as the best form of continued study, it should be our aim in future to create as many institutions as possible, serving exclusively the purpose of medical postgraduate education."

In accordance with these resolutions an International Committee on Postgraduate Education was formed, with the view of co-operating along such lines, which, by concerted action, can be advantageously furthered. For instance, organization of postgraduate instruction in the different countries; widening opportunities; calling the attention of the profession to institutions existing for the purpose; giving information as to the relations of medical colleges to postgraduate study; as to teaching facilities; as to opportunities for wider special postgraduate study; exchange of instructors to enlighten physicians on new important subjects; statistical inquiries; establishment of tours for medical study in foreign countries. This International Committee is to meet in connection with the International Medical Congresses. The American delegation consists of the Surgeons-General of the Army and Navy, Dr. Thayer, of Johns Hopkins, and Drs. Miller, Quintard, and Kast, of the New York Postgraduate Medical School. This subcommittee has not yet been heard from, but is preparing through its secretary, Dr. Kast, a report on the situation of postgraduate instruction in the United States and a plan of action for the next International Congress on Hygiene and Demography to be held in Washington, September, 1912.

I trust that my efforts here to-night may ultimately aid the American delegation.

That there is a demand for postgraduate instruction is abundantly proved by the existence and flourishing condition of the postgraduate schools in this country, the oldest of which was founded in this city nearly thirty years ago.

Let us at the outset define the attitude of the existing postgraduate schools toward this movement. That they are not antagonistic is evidenced by the fact that three members of the American Committee are affiliated with one of the postgraduate schools. These schools cater generally to a class of out-of-

*Read before the Medical Society of the County of New York, March 25, 1912.

town physicians, who give up practice for a period of weeks or months and devote themselves exclusively to postgraduate study. The course at the school is arranged accordingly. They also cater to such as wish to specialize, or wish to become proficient in the technique of cystoscopy, ureter-catherization, *x*-ray or other special work. Those physicians will have to devote their entire time to the various aspects of their particular specialty, and will be obliged to pay for tuition. In Berlin, for instance, paid courses flourish directly adjacent to the courses which are free. The American postgraduate schools have the great advantage of controlling and maintaining well equipped hospitals and laboratories in conjunction with the school, whereby administration and teaching work hand in hand. The hospital is founded and maintained for the purposes of instruction. Their standard of teaching is not higher than that in the fourth year of a first-class medical college. Similar institutions founded for this purpose exist in Germany, Russia, and Great Britain. Tuition is both gratuitous and paid.

In many countries physicians holding public medical offices are required to report for regular postgraduate courses arranged by the Government. Our Army and Navy surgeons are obliged to attend at stated intervals courses at the Army and Navy Medical School in Washington.

Dr. John B. Murphy of Chicago, at this writing President of the American Medical Association, has in his inaugural address even gone so far as to suggest that a license to practise should be granted only for a period of say five to ten years, and at the expiration of this time, physicians should be required to pass an examination or to take a prescribed course of study. Many American physicians go abroad from time to time to continue and extend their studies.

I am sure that all of us at times have felt the need of a brushing-up, and many a practitioner is spending a spare hour in the lecture halls of our medical colleges, side by side with undergraduates. And well may our universities here in New York contribute their share toward the work of postgraduate education. They are well endowed, have ample incomes and every facility for the best teaching available; they have taught many of us and are instructing our sons and daughters; they have the use of city and private hospitals for their students, whereas we physicians and permanent residents of this city are deprived of these privileges. By teaching physicians, university teachers will readily observe whether their undergraduate teaching has fallen on fertile soil, or whether it needs reformation and in what direction. Undergraduate and postgraduate teaching is correlated and should work harmoniously. University teaching and university teachers should never lose the life-giving contact with the practice of medicine.

It is true we have our full quota of medical societies, both private and public, and continue to learn at their meetings. True also we have numerous medical journals, which chronicle the progress in the medical world, as well as original papers—and it is frequently more profitable to peruse such papers at leisure than to listen to them. The American Medical Association, it is true, since 1907 has arranged a four years' postgraduate course of study for County Societies, which covers the entire field of medicine and surgery and is followed by about three hundred and fifty County Societies throughout the United States. While this is a praiseworthy effort, it does not fill the need, and is furthermore not applicable to such large societies as ours.

In our neighboring city of Philadelphia some attempt along this line has been made. There has been in existence for a decade a bi-weekly clinic at the Pennsylvania Hospital open to practitioners; the entire morning is devoted to this clinic, the first half to medical, the second half to surgical work.

Still we have the satisfaction of seeing in our own city examples of the kind of instruction we really need—the Harvey lectures; lectures and demonstration of skin diseases given at the New York Skin and Cancer Hospital by Dr. Bulkley; lectures and demonstrations of orthopedic diseases at the New York Orthopedic Hospital by Drs. Shaffer and Hibbs; clinical conferences at the New York Neurological Institute; demonstrations of newer diagnostic methods of gastrointestinal diseases at the Ward's Island Institutes by Dr. Kemp; demonstration of the neurological material of Lebanon Hospital to physicians of the Bronx by Dr. Leszynsky. Almost all hospital surgeons send out cards to their friends, inviting them to operations personally performed. Some of the courses mentioned above are extremely popular with the profession; some have been abandoned; some, and there may be more than I am cognizant of, are not adequately brought before the medical public to be sufficiently appreciated. They are almost uniformly the result of private initiative.

The Rockefeller Hospital has recently instituted clinical demonstrations to groups of from forty to fifty physicians of such diseases which they are investigating, with the object in view of acquainting the profession with the problems upon which they are working.

Now, let us consider what a city like New York could render to the cause of postgraduate instruction. I feel positive that many physicians have not witnessed an autopsy since leaving college. The greater majority see very little pathological material. We all acknowledge, however, the enormous educational value of post-mortem as compared with bedside findings. This anomalous state of affairs could easily be corrected in our city by utilizing the wealth of pathological specimens to be found in every hospital as well as the enormous autopsy material which is constantly pouring into such institutions as the Russell Sage Institute of Pathology or the city morgue.

An occasional tour of inspection of the hospitals for contagious diseases at the foot of Sixteenth street, of North Brothers Island, of tuberculosis hospitals and sanatoria, would greatly increase our ability to recognize and manage such diseases, and further impress upon us the value of special therapeutic measures, such as the open-air treatment, this merely to mention one instance.

A visit to the quarantine station of our port would illustrate the latest and most approved methods of disinfecting living quarters and clothing. Moreover, such of us as are interested in tropical diseases would frequently find excellent opportunities for observation.

The Rockefeller Institute is the Mecca of every foreign medical visitor. How little comparatively do we New Yorkers know concerning the important original work accomplished within its walls. We could learn there the scope and methods of modern research and see the development of such epoch-making work as the transplantation of organs, the cultivation of tissues outside the living body, intra-

tracheal insufflation anasthesia, the vaccine treatment of meningeal infections, etc., etc.

The Division of Laboratories of our Health Department could teach us new and valuable methods of examining sputum, blood, cerebrospinal fluid, as well as the preparation of vaccines and sera.

The physiological and pharmacological departments of our medical colleges are continually engaged in experimenting with new apparatus and with new and old drugs to test their applicability to practical medicine. A demonstration of results attained would furnish us many a practical hint.

How little is given to the profession of the ever increasing knowledge of mental diseases. Would it not benefit us, and through us the community, to see the material of our island asylums and the psychopathic ward of Bellevue, that great receiving and sifting station for the insane? The enormous clinical material of our asylums, our homes for chronic invalids and incurables, is practically wasted as to its educational possibilities.

Why should not our vast dispensary material be used for postgraduate teaching? That material covers general medicine and surgery, as well as the specialties. It comprises the class of cases which come to our private consulting rooms. These patients generally do not object to repeated examinations. Physicians working in dispensaries are prone to fall into slipshod habits and treat symptoms rather than make a diagnosis. They would quickly awaken to their duties and accomplish far better work if observed and quizzed by fellow practitioners.

However, the main and most important centers of teaching must be our hospitals, both public and private. Our hospitals have heretofore been monopolized by a favored minority, while the rank and file of the profession have been deprived of the incalculably great benefit of hospital experience. This benefit will be especially apparent when the family physician who sent a patient to the hospital, and may have to continue the treatment after the patients' discharge, has an opportunity to discuss the case with the hospital physicians during rounds. At present this is occasionally granted as an act of courtesy on the part of the attending towards individual members of the profession. Why should this courtesy not be extended to all physicians as a matter of just privilege? No one will be the loser, but on the contrary all will gain by such a procedure.

As it is, patients are used in many places for undergraduate teaching. They would surely not be handled less considerately by physicians than they are by students; on the contrary, they would frequently derive some benefit from an interchange of opinion between the attending and the visitors. Furthermore, this material cannot be valued and appreciated by the undergraduates in the same degree as by the practitioners. The house staff will have to do more detailed and more painstaking work on the cases; the nurses will be obliged to attend to their various duties more assiduously. Records will be kept in better and more accurate condition. The attendings will be stimulated to study and read up about their cases. As a consequence the entire work and standing of a hospital will be raised to a higher plane of efficiency. As it is, some hospital physicians are teaching colleagues from other states without compensation; some are teaching undergraduates without compensation; many are only too willing to begin teaching, thereby improving themselves and coming into friendly contact with their brother practitioners. I feel sure that very few physicians connected with hospitals, dispensaries, laboratories, and asylums, would refuse to serve gratuitously as teachers to their local confrères.

This plan has been in operation in many European countries, and is most completely organized in Germany, where it has been in existence since 1900. There the governing agencies have recognized the potent fact that it is to their advantage and for the best interests of the community at large to have physicians as well trained as possible and to keep them in training. The department of education, which controls all schools and universities, supports the movement. Local committees arrange the details of postgraduate work, which is strongly assisted by a special organ, *The Journal for Medical Postgraduate Instruction*. This journal announces the time, place and scope of lectures and courses; prints important lectures, thus making them accessible to those who are prevented from attendance and publishes every detail pertaining to the movement. A Central Committee for the Empire assists the local committees, stimulates the formation of new local unions, collects all available material on postgraduate instruction and acts as a central bureau of information. It conducts its affairs from a large special building, the "Kaiserin Friedrich Haus," in Berlin. This building contains, besides offices, information bureaus and meeting rooms, a large auditorium and laboratories for practical courses in the auxiliary branches of medicine; furthermore, a collection of instruments and material used in medical teaching, such as charts, drawings, wax models, mannikins, projection apparatus, etc., which are loaned to local organizations; also exhibition rooms rented to manufacturers of instruments, appliances and technical products, intended for use in the practice of medicine.

The various states and municipalities give moral and financial support to the movement. The universities open their clinics and laboratories. Everything is gratis to the physician, excepting perhaps in some cities, where a nominal fee of about $1 is charged to the participants for an entire session. The expenses are low, because institutions already existing, hospitals, asylums and laboratories, are used for the purpose, and the visiting physicians give their services gratis.

There is no valid reason why we could not follow this example in our country. It is left to the American delegation of the International Committee to organize this movement throughout the land. I appeal here to-night to the physicians of New York to organize for the purpose of free postgraduate instruction. We have only to decide whether we require and desire it. We need only to remind those upon whose cooperation we depend how important it is that all practitioners recognize promptly and handle properly all forms of communicable diseases. For instance, many physicians have never seen a case of smallpox. Should we not all recognize it and see it again from time to time? Or take tuberculosis. To reduce its ravages and the enormous economic loss entailed by it, we must all be perfectly familiar with the earliest signs and symptoms, must know the value of tuberculin tests, of *x*-ray examinations, and the best methods of percussing the apices—for even in this elementary matter changes and improvements are continually taking place. These details must be demonstrated to the practitioner on the prolific material of special hospitals and sanatoria.

Communities and nations are vitally interested in cutting down their frightful rate of infant mortality. As a campaign measure, physicians must be given opportunity to observe what is best in the ever changing methods of infant feeding and infant care.

Our State Department of Labor requires us under penalty of a fine to report cases of lead, arsenic, and phosphorus poisoning, anthrax, and compressed-air sickness. How many practitioners can now recognize caisson disease, anthrax, or chronic arsenic and phosphorus poisoning? Let the State Department of Labor furnish us an opportunity to see and study such cases as they appear in public institutions, and we shall then be able to cooperate in stamping out industrial diseases.

I am sure the public will welcome and support this movement, realizing fully that it is to their best interests for the practitioners to keep in constant training. There seems to be no serious barriers or obstacles to be overcome. The benefits to all mutually concerned are obvious.

A tentative plan is proposed herewith. A central committee for postgraduate instruction is formed by this society. This committee considers and selects all institutions which can be used for postgraduate teaching. It then appeals to the lay and medical boards of said institutions and enlists their support for this movement. The institutions which agree to cooperate elect a special committee of their own, which arranges the work of teaching in the home institution and confers with the central committee. The latter publishes the time, place, and scope of the demonstrations and lectures with the regular monthly notices on the bulletin board of the Academy and in the medical weeklies, which will undoubtedly open their columns for the cause. The difficult part of the problem is how to accommodate the five thousand or more physicians of this county. It is impossible to predict how many will avail themselves of this opportunity. It is proposed to divide the boroughs of Manhattan and Bronx into districts, and allow physicians who desire to participate to register at the institutions situated in their district. This will gain them admittance in larger or smaller groups according to the subject taught, and in proportion to local facilities. Institutions wishing to present subjects of general interest can give them to the entire profession on their own premises, providing they have spacious auditoria or in the halls of the Academy. The central committee reports on the progress of the movement at the monthly meetings of this society and receives suggestions. Further details may be left to the work of committees.

In conclusion let us bear in mind these fundamental facts so well expressed by Professor Kutner: Medical science is progressing by leaps and bounds. We cannot keep pace with the flood of medical literature. The subdivision into specialties has about reached its limits. Specialism, fruitful as it may be, has a trend to one-sidedness and narrow-mindedness.

Postgraduate instruction, as here propounded, does not propose to train specialists, but to enable the general practitioner to perform his work in the best way possible, by giving him from time to time those modern achievements of our science and art which have been thoroughly tested and accepted. Postgraduate instruction will thus not only benefit the physician in his scientific and economic struggle, but will also enable him to fulfil his high mission of preserving and protecting the health of the nations.

116 East Seventy-sixth Street.

GONORRHEA IN WOMEN.

By MAUDE GLASGOW, M.D.,

NEW YORK.

Gonorrhea has been demonstrated a disease of Protean character; modern methods of research having shown its latency, chronicity, and resistance to treatment after the first stage has been passed; and since Neisser's discovery of the gonococcus, the microscope has proved a first aid in establishing a diagnosis in doubtful and suspected cases.

The gonococcus occurs in groups of two, four, and eight cocci, which are found in typical cases, enclosed within the pus corpuscle, but which are also frequently discovered hanging on to the edge of the epithelial cells, the number of germs present corresponding to the activity and virulence of the infection.

This organism may be stained by any of the basic aniline dyes, and is differentiated from other micrococci of like appearance by its distinctive property of being decolorized by Gram's method of staining, and taking up the counter-stains.

In chronic cases the germ may be very difficult to locate, for while the gonococcus but rarely penetrates to the deeper tissues, it is not evenly distributed, but occurs in circumscribed areas, scattered over the surface of the infected region; the intervening portion being entirely free from this particular germ, though millions of others closely resembling it may be present.

In these chronic cases, therefore, it is necessary to make frequent examinations and to stain several slides. In doubtful cases it is well to have a test specimen on hand, for the purpose of comparison, and if still in doubt, cultures of the organism may be made. The most favorable time for finding the gonococcus is just before or immediately after the monthly period, as the germ multiplies rapidly at this time. Chronic cases are stirred into activity by sexual intemperance, alcoholic stimulation, overexertion, or any excess.

The number of gonococci is vastly increased during the puerperium, and a specimen taken about the fifth day will show large numbers, although before labor their presence may not have been suspected. The youth of the patient always seems to be a factor in the virulence of the disease.

The specimen is obtained by means of a platinum loop, sharp spoon, or even a medicine dropper, the patient being instructed not to urinate until afterwards, as the act of urination washes out the urethra. When absent from other parts of the urethra the germ may be found lurking in the glands of Skene; the vulvovaginal glands also provide a hiding place; and when the infection has apparently disappeared from other parts of the genital tract, it will be found entrenched here, and capable of causing, in a new culture ground, a virulent infection.

The gonococcus is rarely found in the vagina, except in cases of secondary infection, or in children and very young girls, or when the secretions have become mixed with discharges from the cervix and uterus.

When obtaining a specimen from the cervix, all tenacious and glairy discharges must be removed, and the specimen taken from the lining membrane of the canal. When the discharge is scanty it may be difficult or impossible to obtain a specimen, unless some agent is employed to dilute the discharge. For this purpose sterile water may be employed, or a solution of mercuric chloride.

The gonococcus finds its home in epithelial tissues, and when suppuration occurs in connective tissues, associated with gonorrheal activity, it is probably due to mixed infection. Any part of the genital tract may be attacked, but infection occurs in order of frequency, in the urethra, cervix, uterus, vulva, vagina, and rectum, locating in some definite spot.

Inflammation of the endometrium may be confined to the cervix, where it may remain for an indefinite time or until the stimulation afforded by the puerperium, or unwise interference in the way of treatment, may cause the infection to extend further. Bumm believes that the gland structures in this region may escape infection altogether, and it is the opinion of the same authority that in the vulva, when the glands of Bartholin are attacked, the infection may remain confined to the mouths of the glands, unless a mixed infection is present.

The tendency of the gonococcus to occur in spots scattered over the infected regions is very noticeable. These scattered areas of infection are found in the cervix, in the endothelium of the uterus, in the bladder wall, and in the urethra, and it is in the inflamed spots of the latter that the germs when present are to be found.

A. Palmer Dudley points out that while the vaginal mucous membrane is not susceptible to infection, yet the microscopic picture shows minute red spots, from which a grayish discharge issues on the mucous membrane of the posterior vaginal wall: probably due to secondary infection of the uterus.

Even when no secretion is visible germs may still be present. Infections occur after treatment and apparent cure, and the infected individual transmits infection at one time and not at another.

Gonorrhea is not merely a local disease, for it may cause a general toxemia, manifested by undefined recurring pains in the pelvis, lack of energy, anemia, debility, and general invalidism. It may also attack any organ or joint in the body, but metastases are most likely to occur during, or following the puerperium. The menstrual function is interferred with, the periods become painful, irregular, and profuse; leucorrheal discharge is a frequent symptom, there may be irritation of bladder and rectum, while pelvic tenderness and pain are common symptoms of the disease.

The gonococcus is very tenacious of life, and may remain quiescent for very long periods still retaining its vitality, so that when stimulated into activity by the usual causes, or when passed through a new culture ground, it manifests all its pristine vigor and virulence. It frequently happens, therefore, that when a man marries, who believes himself cured of gonorrhea, he infects his wife, who in turn reinfects her husband with the germ he gave her, which now runs the course of a new infection.

The vitality of the gonococcus is so marked that it has been obtained in secretions, contained in infected clothing, six months after the original infection. Even when the germ has apparently disappeared from the tissues and is not found in the secretions, it cannot positively be stated that the gonococcus is not present.

A legacy the germ is likely to leave behind as a mark of its former presence is a change in the appearance of the meatus urinarius, which assumes a red and pouting appearance like a caruncle; while small, red, inflamed spots remain for years to mark the mouths of the glands of Bartholin.

An attack of gonorrhea runs an acute course of from six to eight weeks, after which it passes over into the subacute and chronic forms. The vulvovaginal glands which are frequently attacked may escape for weeks or months, one being affected first to be succeeded by the other. When the cervix is invaded, the disease may remain latent indefinitely, and in a certain number of cases the infection does not extend above the internal os; and when the uterus is attacked, the tubes may not be reached, under ordinary circumstances, for months or years, although they have been reached in as short a time as two weeks.

A latent infection becomes active in the puerperal state, when, after her long months of patient endurance and the agony of parturition, the woman pays the price of her maternity in future sterility and perhaps invalidism as well, in many cases. Instrumental interference may also rouse a latent infection, and cause its rapid extension, or the infection may be carried to other parts directly by the instruments used.

When the uterus and appendages are infected, when there are frequent exacerbations in which the patient suffers acutely, when rest in bed and prolonged hot douches give but temporary relief, the only remedy is ablation of the diseased organs, a price the woman is so often finally forced to pay. After years of ill-health and suffering, when she finds herself a feeble, worn-out nervous wreck, and life a burden, then she seeks the dreaded operating table, and leaves it a deformed multilated, sexless creature, an object of commiseration to all who know her history. Castration in man is regarded as a humiliating, degrading operation, tending to embitter the subject of it against society, and is not resorted to even in the case of criminals. But women are every day castrated who are not criminals, but the very flower of womanhood, and they are compelled to undergo this unsexing operation not for their own shortcomings but for those of others.

If women voluntarily exposed themselves to disease which would result in sapping the husband's vitality, energy, and strength, making him a dependent invalid, or subjecting him to the surgical shock of an operation with consequent multilation, or in some cases even death itself, would men be willing to continue to so suffer, and would they invoke the aid of the medical secret to protect women in the exercise of this so-called freedom which cost their partners such a heavy price? Viewed in the cold light of reason and logic, if the so-called medical secret permits and conceals these ghastly crimes, making of the physician an accessory after the fact, can men of sound judgment and clean lives permit themselves to be governed by it? Would they be so governed if their own lives were so played with?

A disease so insidious in onset and so difficult to eradicate has naturally been subjected to many and divers methods of treatment, and from the number of remedies suggested and the various methods of their application, it is easy to infer the results of treatment. In women there is often entire or partial absence of symptoms in the first stage; but when seen in its incipiency, which is not very often, the consensus as to treatment is the adoption of conservative measures. Frequent but misdirected efforts in the way of examinations and applications to urethra and cervix, through instruments and otherwise, are more likely to cause the disease to extend than to remove it. Rest in bed is most im-

portant at this stage; the patient is kept on a bland unstimulating diet, the bowls kept freely open, and the bladder and urethra well flushed out—not by irrigations, but by copious draughts of diluent drinks. The vagina should be kept flushed out with hot alkaline douches, and it may be added that at any stage of the disease, the results of treatment will be more satisfactory if the physical condition of the patient is intelligently cared for.

The subacute and chronic forms admit of more active treatment; astringents and antiseptics are in order at this stage. Infected areas in the urethra, but not the whole surface, are treated with the usual remedial agents through an endoscope, special attention being directed to the glands of Skene. The ducts of the vulvovaginal glands are cauterized when necessary, and, in case of abscess, excised and drained. When the cervix has been attacked and its glands infected, the latter must be destroyed. This can be done by cauterization, with the actual cautery, or pure lactic acid may be used and applied in successive treatments.

When the uterus is infected, any intrauterine application or curettage, unless in case of hemorrhage, is likely to carry the infection to the appendages. It is impossible to reach every part of the uterine surface by curette, and the parts left unmolested may be those where gonococci most abound. If even local treatment to an infected uterus, applied to the vaginal vault, will provoke an exacerbation, one can conceive the grave danger which may result to the patient by the use of the curette, or the intrauterine applicator, as a routine procedure.

Infection of the rectum, which is found in about eight per cent. of cases, is treated by the applications of the silver salts in conjunction with opium; to be followed by treatment with astringents. The value of the vaccine treatment in gonorrhea has not yet been established, but there are many favorable reports of it. It is not difficult to administer, and in certain selected cases will no doubt be of great benefit.

Gonorrhea is one of the most prevalent of diseases, besides being one which menaces the life and health of many innocent women. It is one from which the state affords her no protection, though unlike man she is in most instances unable to protect herself from the contagion.

As a very large percentage of men have at one time or another suffered from gonorrhea, and many of those have not been cured of the disease, and as most infections arise from these chronic cases, it is evident how futile the treatment of gonorrhea in women must be, unless the infected members of the other sex also receive treatment; for if a man is continually reinfecting his wife with fresh germs, treatment of the latter can be of but little benefit.

In Hamburg no matter to what social class a man belongs, if he is accused of infecting a woman with venereal disease, he is obliged to undergo official examination, and if diseased is obliged to receive appropriate treatment, either in the hospital or elsewhere.

The Scandinavian countries have taken the lead in instituting measures for the protection of their citizens from venereal disease. Here the authorities, by means of notification, are kept constantly informed of the extent and fluctuation of those disorders, and veneral disease is dealt with as other contagious diseases are. The treatment of any kind of a communicable disease is regarded as a sanitary question, and dealt with accordingly.

These measures have been as remarkable as they are gratifying in their outcome, and they have resulted in a very marked diminution of venereal disease. Gratuitous treatment is provided, and made easily accessible to all. Probably it is but a question of time when the methods of Scandinavia will be introduced into all civilized countries.

THE MOVEMENT FOR INTERNATIONALISM IN MEDICINE AND HYGIENE.

By KARL M. VOGEL, M.D.,

NEW YORK

ASSISTANT PROFESSOR OF CLINICAL PATHOLOGY, COLUMBIA UNIVERSITY; ASSISTANT ATTENDING PHYSICIAN, ST. LUKE'S HOSPITAL.

One of the results of modern conditions in the industrial world has been to compel those conducting large enterprises to devote more and more attention to securing efficiency of organization. The ordinary details of production having been developed to the highest possible pitch, success or even continued existence requires that the various units composing the body of a business shall be so correlated as to work in harmony and accomplish results with the least possible reduplication of effort and the maximum of cooperation, while the larger the scale of the operations the more essential does it become to have the mechanism of production and distribution work with a minimum of lost motion. Although the problems of intellectual progress are of course hardly comparable to those of commercial affairs, something of an analogy does exist, and it is very evident that as at present carried on "science," using the term in its broadest sense, is being managed in a highly wasteful and inefficient manner. The activity of individuals is enormous, but their energies are often misdirected and expended uneconomically through the absence of an adequate scheme of coordination. The benefits in this direction that have resulted through the efforts during recent years of such centralizing organizations as the American Medical Association, the American Association for the Advancement of Science, the American Public Health Association, and the American Chemical Association, require no comment, but there is no doubt that a further development of the same principle through a closer and more authoritative association of international societies is imperative. This idea is of course not new, but steps toward putting it into practice are of comparatively recent date and for those who have not followed its growth it is astonishing to learn how much has already been accomplished. There are in existence over six hundred international societies of the most varied interests, and international congresses are held annually by the score, but the results are far from commensurate with the labor expended—chiefly through the lack of any sort of systematic supervision or correlation. The work of the International Peace Tribunal at The Hague is familiar to every one, but it is not so widely known that in the same city there has existed for several years another organization which is perhaps of no less importance in its bearing on international relations and is certainly more concrete in its aims. This is the "Fondation pour l'Internationalisme," intended to meet the need which has just been indicated. The development, objects, and achievements of the foundation are described in detail in two volumes published under its auspices: "L'Internationalisme Médical" and "L'Internationalisme Scientifique," written by Dr.

P. H. Eijkman, director of the Foundation and president of the Netherland Röntgen Ray Society. Two international supervisory bureaus have already been in existence for some time, the "Bureau de la Commission Permanente des Congrès Internationaux de Médecine," established in 1909, and the "Bureau Permanent de la Federation Internationale de Pharmacie," established in 1910, while a third the "Bureau Permanent de l'Institut International de Statistique," has recently been added.

This movement for securing greater efficiency of organization is of especially vital interest to the medical profession, for the science of medicine is undoubtedly international in its scope, development, and needs to a greater degree than any other branch of learning. Medical research is being pursued more intensively and by greater numbers of workers than is the case in any other field of investigation and thorough familiarity with the most recent advances in all quarters of the globe is so essential both in the laboratory and at the bedside that the subscription lists, and in many cases the editorial boards, of all the great medical publications have a truly cosmopolitan character. It is not astonishing, therefore, that though the last twenty-five years have seen the formation of great numbers of international organizations of the most varied sorts, they are by far most numerous and active in the domain of medicine. Indeed there has been what might almost be termed an over-production in this direction, an excess of zeal, that has to some extent defeated its own ends, and through lack of systematic cooperation has led to waste of time and energy, or at least to their inefficient application. That this is so has been demonstrated by the universal recognition of the utility of the Bureau Permanent des Congrès Internationaux de Médecine, established at The Hague for the supervision of future congresses by the international congress held in 1909 at Budapest, and the progress that has been made in this direction has revealed the desirability, in fact the necessity, for the extension of its field of action by the foundation of a central organization that shall serve in a governing or advisory capacity for all the international societies concerned with medicine or allied subjects. It is true especially of projects depending upon international support that they can be carried on successfully only if they meet a distinct need and if the conditions under which they are to exist have been adequately considered. The "Fondation pour l'Internationalisme" has now been in existence a sufficient number of years and has given the subject of internationalism in medicine such exhaustive study as to ensure the wisdom of the methods by means of which it seeks to bring about efficient international cooperation in this field.

It is to the French that the credit must be given for having organized the first international medical congress, held in Paris in 1867. Since that time sixteen in all have been convened in fifteen different cities, and from their modest beginnings they have grown until the one at Budapest in 1909 comprised no less than twenty-one sections. In addition to these reunions on a large scale, however, others pertaining to almost every conceivable special branch have been organized in constantly increasing numbers, so that now international associations holding regular sessions may be counted by the score. Gratifying as this development of international scientific comity has been, it in a way represents a waste of energy, for the unwieldy proportions to which the general congresses have grown tend to make the smaller organizations with their simpler executive machinery more attractive and more useful to their participants, while to some extent the latter meetings also work to the detriment of the former. The need for a centralized bureau to harmonize and simplify the details of organization, to supervise the programs, and by its equipment and experience to lessen the labors of the local committees is manifest, and it is this function that the Bureau Permanent des Congrès de Médecine has assumed. In addition to the medical bureau, that of pharmacy, and that of statistics, already founded, it is now desired to establish bureaus of hygiene, pure sciences, and technology. So far all the expenses of the foundation have been borne by the Dutch government, but as the work develops it is incumbent upon the other powers to follow the enlightened example set by the enterprising people of the Netherlands by contributing material support. Within the scope of the bureau as planned would come such highly important functions as the establishment and publication of an international system of bibliographical records, the organization of concerted action against such evils as the anti-vivisection movement and irregular forms of medical practice, the encouraging of cooperation among medical journals, the appointment of commissions to investigate special questions or the outbreak of epidemics, the consideration of matters pertaining to medical education, nomenclature, the material aspects of professional life, etc.

Undoubtedly under the direction of such a central bureau the number of different organizations would diminish, a most desirable result, for those remaining would gain in strength and utility, while at the same time a wider range of subjects would be represented. The plan as projected provides for the formation of a central bureau having as its nucleus the present Bureau Permanent des Congrès Internationaux de Médecine, 10 Hugo de Grootstraat, The Hague. This will be aided by national committees formed under the auspices of the various local academies of medicine, the faculties of the universities, and especially the medical societies, both general and special. These national committees will send delegates to the international committee which will then deliberate on the matters previously studied and propounded by the national committees. Commissions will be appointed, a bulletin in several languages be published, and the organization of international meetings will be managed by the local committees of the country in which the session is held, under the guidance of the central committee as regards the questions to be discussed, etc.

The international bureau of hygiene which the Foundation hopes to establish shortly is to be organized on similar lines and will serve the purpose of systematizing the work done in the numerous and varied fields that are now integral parts of the study of sanitary science. Public health problems are particularly international in their scope, and it would be highly desirable to have the International Congress of Hygiene and Demography which meets in Washington next September take definite action in support of the project. The cooperation of the most prominent hygienists has already been secured and it is to be hoped that American men of science will take an active interest in furthering a movement whose objects are at once so intensely practical and so intimately associated with the general advancement of knowledge.

ULTRAMEDICAL OR ULTRASURGICAL TREATMENT FOR ECLAMPSIA?

A VERY few decades ago puerperal eclampsia was regarded on all sides as an affection with a practically guaranteed high average mortality under any any every plan of treatment. The large number of theoretical viewpoints as to the nature of the disease seemed to justify the employment of the most diverse measures of treatment. The fact that seemingly moribund patients recovered under many plans of management has been responsible for their continuance even in the absence of sound theory and perhaps at times in opposition to all tenable theories. But whenever any plan was tested on a sufficiently large material, and year in and out, it became apparent that the disease varies much in severity with the particular locality and year, and it began to appear that any real advances in therapeutics must necessarily be extremely hard to appreciate. There can, however, be little doubt today that the mortality of eclampsia has slowly been brought down by strict adherence to two completely opposed plans of treatment, which may be termed the ultrasurgical and the ultramedical. To whatever degree eclampsia may depend on a general pregnancy toxicosis it is recognized that its efficient cause is really labor itself or better the uterine contractions which comprise the latter and which may precede or follow it to a certain extent. Both this fact and the possibility that the fetus and placenta may be the source of toxic material appear to demand the immediate evacuation of the uterus. This was accomplished at first by the simpler means of hastening labor and eventually by accouchement forcé in the widest application of the term, even including vaginal and abdominal hysterotomy and hysterectomy. There seems no good reason to doubt that much life, maternal and fetal, has been saved by these heroic measures. Surgery has not stopped here, for in certain cases where renal stasis seems to prevent the hope of recovery the kidney itself is attacked by the operation of decapsulation. Comparatively recently the mammary glands as a probable source of the toxemia have been excluded provisionally from the circulation by a subcutaneous operation.

At a recent meeting of the Berlin Gynecological Society (*Berliner klinische Wochenschrift*, March 18, 1912) the veteran Olshausen spoke very pessimistically about eclampsia. We know nothing, he said, of its nature and hence have no rational treatment. Rapid evacuation of the uterus, an empirical measure, has secured about one-third better results than were obtainable before its introduction. We have allowed a valuable resource of the past to fall into disuse; this is bleeding up to 500-600 c.c. In discussion it was suggested that the benefit derived from cutting operations was due really to the coincident loss of blood.

The medical treatment has been tested only on a relatively small material, but has been followed up for years in certain localities with enough betterment in mortality percentages to startle those who have never seen the reports. Stroganoff has now treated about 400 cases with his narcotic method, which aims solely at jugulating the convulsions by a graduated use of morphine and chloral so given as to seem the greatest possible economy in dosage. The patients are also strictly isolated from the outer world in every possible way. The mortality at his hands has been but a fraction over 6 per cent. In the United States some of our leading obstetricians are depending upon the use of veratrum viride which by lowering the high blood-pressure which appears to underlie the convulsions serves also to suppress the latter. Low death percentages have been secured under this plan. The only criticism of these figures is found in the claim that in certain favored localities eclampsia is much less malignant than in others.

If puerperal eclampsia is really an example of anaphylaxis and not an ordinary toxemia the rational treatment should be somewhat modified. In an anaphylaxis the patient is not menaced by a large amount of toxic material which necessitates all sorts of meddlesome eliminative procedures. She has simply become sensitized during an earlier pregnancy or during the early stages of the present pregnancy to substances normally present in all gravidæ. Whether or not an anaphylactic shock proves fatal will depend in part on factors entirely beyond our ken. The naturally high mortality of the analogous affection in cows has been practically wiped out by insufflation of air into the milk ducts. The German farmer no longer troubles to send for the veterinary but inserts a turkey quill into a milk duct and by means of his bicycle pump forces air into the latter. But in the cow, at least in the severe type of eclampsia, convulsions do not occur, but instead a collapse or, as it is commonly termed, a paralysis. From all points of view the convulsions seem to be the real object of treatment in mankind. The uterine contractions beget the convulsions. If these be made to cease by rapidly evacuating the uterus the prognosis is good. The earlier in the history of the convulsions the uterus is emptied the better the results. On the other hand, it may be possible to control the convulsions without greatly interfering with labor. This may be effected by keeping down the blood-pressure (by veratrum or copious venesections) or by so benumbing the reflex activity with narcotics that convulsions no longer occur. There are other pernicious factors aside from blood-pressure and convulsions which are reached by neither the ultrasurgical nor the ultramedical plans of treatment. But it will doubtless be found that cases of this sort

occur largely in those patients who have exhibited pregnancy toxicosis long before term. Some of these women, if not most of them, could have been saved by early interruption of pregnancy.

THE GRADGRIND VIEW OF EXISTENCE.

A State Board of Health recently estimated the value of a baby at $1,000—a rash proceeding in a governmental office, such as depends for its existence upon the will of the citizen body; for what native parent would estimate his offspring at any such ignoble figure, or at twenty-fold such figure? A college professor held the above money estimate to be too low; that a baby—the supremest cosmic product—is worth at least $150,000; while another college professor held the value of a man to be but $20, upon which humiliating basis dealing in babies at $4,000 apiece would be a decidedly losing investment. These extreme differences in estimate seem to have been by reason that they were founded upon statistics—one of the most faulty and illogical methods of arriving at any conclusion. For, as everybody knows, any opinion, no matter how perverse or extreme, can somehow get itself backed up, to the satisfaction of its promulgator at least, by statistics.

But if such conclusions based upon statistics are vague, the method of evaluating human life recently proposed by a German scientist is both simple and accurate beyond peradventure. Assume a body to weigh 150 pounds; our Teutonic confrere puts down its fat content as worth $2.50. Of iron there is in such a body hardly enough to make an inch rail. But there is something more worth while when we come to lime; while we have sufficient phosphorus for the making of 2,200 matches, and enough magnesium to set off a very fair display of fireworks. In a 150 pounder there is as much albumin as may be found in 100 eggs, besides a small teaspoonful of sugar and a pinch of salt. On such computation the average man or woman should come up to $7.50; some of us would come up to more than that—even to $10; while a 300 pounder might be worth the price of an overcoat; that is, late in the season when garments are marked down. We are not informed whether the investigator made his calculations according to German trade standards (which are lower than ours), or whether he computed according to the average of prices over a long range of years or according to the present high cost of living.

Of course, all this is absurd; and one does indeed feel ridiculous to learn that he is worth considerably less than the clothes he has on—less, indeed, than just an ordinary suit of "hand-me-downs." Why, again should one seek to fix the value of a baby in dollars and cents; one excuse for this procedure seems to be in order to explain that so many infants' lives are lost (or saved as the case may be) and then to multiply the number by some such arbitrary amount as $4,000, thus showing the commercial profit and loss. And yet there seems to us something very seriously wrong with a civilization which would put a money—a Gradgrind—value upon entities which it were essentially impossible to evaluate upon any material basis. Whether the agitation is for pure milk, or for safety appliances in industry, or for tuberculosis prophylaxis, it seems to be assumed that the body politic cannot be suitably impressed unless the matter is presented in monetary terms.

Now, if it is really true that humankind cannot be got interested in human welfare unless the saving in money can be figured out and presented, there would seem to us to be something very wrong. This new procedure (some speak of it as a habit) of interpreting humanity in money values is on reflection downright coarse and unutterably mean. Besides, it is surely a fruitless procedure; for what normal mind would be impressed by arguments based on such evaluation. How futile is it to represent that every death from consumption means a loss of so much money; or that every child over the age of two has a capital value of so many thousands of dollars. What every consumptive's death really means to any wholesome mind is the extinction of a precious life, the blighting of living hopes and ambitions, the closing of a human account written in nights of despair and in broken and anguished hearts. On the other hand, every child's life over the age of two or of any age really means an actual sentient existence, expanding to the possibilities of a Lincoln or a Milton or a Florence Nightingale.

OPIUM TAKING IN THE FAR EAST

In the temperate zone opium is regarded as a dangerous poison and one which should be used only as a drug. The addiction to opium rapidly develops into a serious vice from which the unfortunate victim is rarely able to escape. The case is altogether different with the Oriental, who uses opium in the same way as the white man uses tobacco. Small quantities of the drug are used daily and in the great majority of cases there is no desire to increase the dose. For example, Dr. Adrian Caddy, in a paper dealing with life insurance in India and read before the Life Assurance Medical Officers' Association on March 6, 1912, stated that in India the confirmed opium fiend is less frequently encountered than is the drunkard in European countries. Opium is most frequently used by people in India after the age of forty-five. It is almost invariably eaten. In China the drug is smoked and there is a difference of opinion as to which is the more injurious habit.

S. B. Neill, actuary of the China Mutual Life Company, read a paper on opium smoking before the opium commission sitting at Shanghai in February, 1909. His figures dealt with 13,336 lives under observation and 549 deaths. The summary of his result was as follows: (1) The mortality experienced by opium smokers is heavier than that experienced by non-opium smokers. (2) Opium smoking is more injurious in tropical than in subtropical or temperate climates. (3) Though it would be difficult to trace any particular death to opium smoking, nevertheless it is probable that the digestive organs are primarily affected by the habit and the smokers become emaciated and lose weight.

Vincent Richards, as the result of an investigation of the opium problem in Balasore, Orissa, found that one in twelve or fourteen of the population used

opium. Of 613 opium eaters examined by him the average age at which the habit was begun was from the twentieth to the twenty-sixth year for men and from the twenty-fourth to the thirtieth year for women. Of the total number 143 had eaten opium for ten to twenty years, 62 for twenty to thirty years, and 38 for periods longer than thirty years. The majority took it daily, morning and evening, the dose varying from 2 to 46 grains daily, the average dose being 5 to 7 grains daily. In the case of large initial doses there was usually a gradual increase, but when the initial doses were small there was usually no increase in the size of the dose. The increasing dosage was usually prompted by a belief in the aphrodisiac power of opium, in its efficacy in the treatment of malaria, dysentery, rheumatism, hemoptysis, and elephantiasis. Richards concluded that the moderate use of opium caused no appreciable ill effects beyond a weakening of the reproductive powers.

GOUT WITHOUT PAROXYSMS.

The apparent infrequency of gout in the United States may be explained in various ways. First, it may be claimed that it is not infrequent but only appears so; and that if a large material of miscellaneous subjects was examined carefully for evidences of gout the latter would be forthcoming. Again, it may be stated that since gout is a metabolic disturbance closely allied to other conditions, the latter may appear as gouty equivalents in the shape of glycosuria, eczema, and such like evidences of retarded metabolism. The statement is also made at times that actual gout is of common occurrence, but is miscalled, the diagnosis being some form of articular rheumatism or other arthropathy. It is not unusual to see tophi in the ears of subjects not known to be gouty. Finally, it may be asserted with plausibility that gout occurs frequently, but in such mild atypical forms as to indicate simply a diathesis and not a frank disease.

The latter appears to represent the views of some German clinicians as to the occurrence of gout in their country. At a recent session of the Hufeland Society, Berlin (*Berliner klinische Wochenschrift*, March 4), Goldscheider outlined these mild atypical forms, which he believed to be of very common occurrence. Virchow made the same claim in 1884, and recently His has revived the opinion. In this form of gout paroxysms or crises are absent. A characteristic symptom is creaking joints. The latter behave as if they had sand in their bearings, which, as a matter of fact, is literally the case, for the condition results from a minimal deposit of uratic sand. Small tophi may be found in certain localities, as the olecranon process. Arteriosclerosis not only coexists, but is itself an expression of the gouty state. When all other causal factors in the genesis of arteriosclerosis may be excluded the condition may be set down forthwith as of gouty origin. Chronic nephritis with a history or evidences of gravel, is also significant of gout. In the absence of nephritis the combination of obesity and gravel has the same significance. Of additional value as a hint in the same direction is abdominal plethora. Evidences of secondary neuropathy in a subject not of neurotic temperament are highly significant, and there is a special disposition to angioneurotic paroxysms. Hence these subjects tend to suffer from migrainous attacks, neuralgias, spells of insomnia, and depression. Finally these subjects come of stock which presents the same symptom complex.

Nature of Dermatitis Herpetiformis.

When Duhring first described the disease sometimes designated by his name, conservative dermatologists who objected to the introduction of new disease concepts were inclined to look upon the affection as an aberrant form of pemphigus, and, despite the manifest differences between the former and the grave forms of the latter, this assertion may, in the absence of a known efficient cause, still be regarded as unanswered. At a recent meeting of the Aerztlicher Verein of Marburg (*Münchener medizinische Wochenschrift*, January 23), Hübner reported two cases which presented themselves at about the same time. One patient improved remarkably under Fowler's solution, his disease thereby showing notable analogy with pemphigus; for in the main Duhring's disease does not benefit much by arsenic. The author was then moved to test the disease with salvarsan by intravenous injection. The immediate result was brilliant but short lived. An intramuscular injection was then given, with the consequence that the patient underwent steady improvement. He was not cured, but the bullous element of the affection vanished, leaving only an itching erythema or urticaria. As is well known, the eruptions may begin in this fashion before blebs develop, and the milder lesions may also coexist with the latter. The author states that the bullæ which appear in Duhring's disease resemble exactly those of pemphigus, and that practically they occur in no other disease. The prompt response to arsenic, as seen in the author's cases, is a further point of agreement. It therefore seems possible to associate the two affections more closely than has heretofore been done.

Serotherapy of Typhoid Fever.

Typhoid fever is one of the numerous family of bacteriotoxemias in which theoretically there is little to be expected from the use of antisera. The success of vaccinoprophylaxis in this affection has also aroused hopes that it will soon be possible to eradicate it by immunizing those most exposed to it. Nevertheless the effort to discover and prepare efficacious sera for diseases of this character seems to be more earnest than ever before. As an example Lüdke of Würzburg announced at a recent meeting of a local medical society (*Berliner klinische Wochenschrift*, March 11) that he had succeeded in preparing a serum which behaved specifically in typhoid. His first step was to secure the bacteriotoxin. The culture had grown for about two weeks in alkaline bouillon. It was then filtered out, triturated, and digested with pepsin and hydrochloric acid. A highly toxic fluid was thus obtained, and by immunizing goats and small laboratory animals with small doses an antitoxin was obtained. He next prepared a bactericidal serum by treating the animals with living cultures and combined the two sera. The mixed serum was tested on twenty-nine typhoid patients. Leaving out of consideration fifteen advanced cases there were fourteen tested relatively early. In ten of these the disease seemed to

have been fairly aborted, as permanent defervescence supervened in from two to four days. The theoretical requirement thus seems to be borne out, for it has generally been asserted that only a mixed serum of this character, injected very early in typhoid fever, could be expected to modify the course of the disease.

News of the Week.

A Meeting Hall in Washington.—The U. S. Senate, on Monday of this week, agreed to Senator Root's bill setting apart the old Pennsylvania railway station site at Sixth street, N. W., and the Mall as a site for a George Washington memorial building to be used as a "gathering place and headquarters for patriotic, scientific, medical, and other organizations." The bill retains to the Smithsonian Institution the control of the building when it is erected and prescribes that the building shall cost not less than $2,000,000 and be erected by the George Washington Memorial Association after plans to be approved by the Committee of Fine Arts. It will have an auditorium with a seating capacity for 6,000 persons and a permanent endowment of $500,000.

Reciprocity in State Licenses.—The Pennsylvania State Bureau of Medical Education and Licensure recently completed an agreement on medical licenses to be offered to other States. The basis for reciprocity is as follows: Licenses earned by examination; reciprocity is only to apply to holders of diplomas from medical colleges recognized as in good standing by the licensing authorities of the State in which the candidate seeks the right to practise; the licensing authorities of either State are to follow the laws of their State in rating preliminary education; a regularly licensed practitioner applying for the benefits of reciprocity must have been in practice at least two years in the State from which he holds his license, but the licensing authorities of either State may in their discretion modify this requirement in any individual case; the applicant shall not have failed in any medical examination conducted by licensing authorities of the State in which he seeks to be licensed; the applicant must appear in person before examiners, present satisfactory evidence of character and that he is not addicted to the intemperate use of drugs or liquors; credentials as to personal and professional standing shall be required from medical society of the county or State in which applicant has been practising. The examination of candidates for State licenses was ordered to begin on June 24 at Philadelphia, Harrisburg, and Pittsburgh. The examination for second year medical students was changed from May 24 to June 27.

Medical Examinations in Illinois.—The State Board of Health of Illinois reports that during 1911, 432 licenses to practice medicine in the State were granted, the number of examinations being 646, and the percentage of failures 33. This is the highest percentage of rejections in the history of the board and indicates an increase in the requirements. Of the 179 osteopaths and other followers of "drugless healing" who appeared for examination during the year, only 61 were successful. Osteopathy has no official recognition in the State, and the examination given them by the board is the same as that given to other so-called "drugless healers" and embraces no form of treatment, the subjects covered being physical diagnosis, pathology and bacteriology, hygiene, chemistry, anatomy, and physiology. The board also reports that licenses were granted to only 47 midwives out of 178 who were examined.

"Health Day."—At the instigation of the Women's Temperance Union the Governor of New Hampshire recently proclaimed a "Health Day," the object being to interest every individual to improve sanitary and hygienic conditions and to emphasize right methods of living whereby the health of the community might be permanently benefited. The response was gratifying; the newspapers published health articles, programs were given in the public schools in furtherance of the idea, and the results have convinced the originators of the value of setting apart such a day.

Texas Quarantine On.—In accordance with annual custom the Governor of Texas issued a proclamation declaring a quarantine, effective on April 1, on the Gulf Coast and Rio Grande border, applying to all vessels, railway trains, persons, or things, coming from places infected with yellow fever, smallpox, bubonic plague, or cholera. All places south of 25 degrees latitude are considered as infected until proof to the contrary is furnished.

Unreported Births.—A house to house census enumeration of the infant population of Louisville, Ky., now under way, has disclosed a laxity in reporting births to the Registrar's office. In three days forty unregistered infants were found, and the names of the physicians failing to report them have been sent to the State Board of Vital Statistics.

Albany Express Held.—The health officials of Springfield, Mass., held up the Albany express for nearly two hours on April 9 while a thorough examination was made of a child who was suspected to be suffering from smallpox. The sixty passengers in the car in which the child was traveling were locked in until it was decided that the disease was chickenpox.

Gas Well Bought.—The State of New York recently acquired the last of the gas well properties north of Saratoga, the pumping of which seriously threatened the existence of the springs at Saratoga. The Legislature provided some time ago for the purchase of all the springs by the State.

Vacancy in Illinois State Service.—On May 17, 1912, the Illinois Civil Service Commission will hold in Chicago an examination for the position of factory physician in the State service. The examination is open to citizens of the United States, both men and women, over twenty-one years of age. The salary is $125 a month and traveling expenses. The examination will comprise: training and experience, 3 points; and special subjects, including medicine, occupational diseases, pediatrics, and gynecology, and its relation to factory work, 7 points.

Children's Bureau.—President Taft on April 9 signed the bill creating in the Department of Commerce and Labor a children's bureau, thus establishing Federal supervision over child welfare.

Nurses Graduate.—Thirty young women received diplomas as trained nurses on April 8 at the commencement exercises of the Margaret Fahnestock Training School of the Post-Graduate Hospital, New York. Dr. Wendell C. Phillips, president of the State Medical Society, presented the diplomas and addressed the nurses.

Bellevue Post Vacant.—The position of general medical superintendent at Bellevue Hospital, which has been temporarily filled by Dr. George O'Hanlon, has been declared open for an appointment. The post carries a salary of $5,000 a year and household accommodations. The Municipal Civil Service Commission has prepared a list of those eligible for appointment.

Farm for Inebriates.—The Board of Estimate of New York City recently considered the report of a committee appointed to select a site for the proposed city farm for inebriates, but took no action. The committee recommended a tract near Smithtown, Long Island, consisting of 523 acres, which is held at $225 an acre. The board laid the matter over until a farm in Orange County, consisting of 640 acres for $75,000, could be investigated. The water supply of both sites was also under consideration.

Seaside Hospital.—The Association for Improving the Condition of the Poor has offered to erect and equip, at a cost of $250,000, a hospital for children suffering from non-pulmonary tuberculosis, on condition that the City of New York provide a seashore site and own and maintain the hospital when it is completed. It is desired to build the hospital at Rockaway Park on land recently acquired by the city, and tentative plans have been drawn so that if approved by the Board of Estimate construction can be begun at once. The association estimates that between 4,000 and 5,000 children of the poor in this city suffer from tuberculosis of the bones or glands, and the Sea Breeze Hospital, which it has maintained since 1904, is now inadequate to meet the demands made upon it.

Addition to Hospital.—Houston Memorial Ward of the Chester, Pa., Hospital was formally presented to the managers on April 10 by Mrs. Margaret A. Houston, widow of Charles B. Houston, and mother of former Mayor Howard H. Houston. The ward is intended for the care and treatment of children up to the age of 12 years. The new building is octagonal in shape and connected with the main institution by an overhead sun parlor, which communicates with the second floor, designed as a play-room and dining-room.

Volunteer Hospital.—Through its president, Ballington Booth, the Volunteer Hospital of New York reports a successful year, during which the present quarters at 93 Gold street have proved to be inadequate. A fund to provide for the erection of a new building has therefore been started.

Oneida County Hospital.—Governor Dix recently signed a bill providing for the maintenance of a general hospital for Oneida County, New York, which will be open to all citizens of the county whether able to pay or not. The control of the hospital will be vested in a board of managers, who will have entire charge of the hospital subject to the Board of Supervisors, who will provide the funds. Heretofore the only public hospital in Oneida County has been operated in connection with the Almshouse.

Charitable Bequests.—By the will of the late Captain Louis Hillebrand of Philadelphia the Pennsylvania Hospital and the German Hospital in that city each receive the sum of $1,000. Harvard University has announced an anonymous gift of $5,000 to establish the Lawrence Carteret Fenno memorial free bed in the Collis P. Huntington Memorial Hospital. The University of Texas has under consideration an offer from Mrs. John Sealey of Galveston of a sum of money for the erection in that city of a new building for the medical department of the university. It is understood that the offer is for $50,000 and that it will be accepted. By the will of the late Thomas W. Haldom of Philadelphia, the sum of $5,000 is bequeathed to the Children's Hospital for the endowment of two free beds. A residuary bequest is made to the Pennsylvania Hospital of $5,000, also for the endowment of a free bed.

Dr. William C. Gorgas, chief sanitary officer of the Isthmian Canal Commission, will be the principal speaker at the annual commencement exercises of the Johns Hopkins University, Baltimore, in June.

Dr. Henry A. Christian has resigned the post of physician-in-chief to the Carney Hospital, Boston, and expects to go abroad on April 30 to study Epropean clinics. Dr. Christian was recently appointed chief physician to the new Peter Bent Brigham Hospital of Boston.

Class Reunion.—The 20th anniversary banquet of the class of 1892 of the New York University Medical College was held at the Hotel Martinique, New York, on April 3. The class originally numbered 162, 9 of whom have since died. Dr. Robert E. Coughlin of Brooklyn acted as toastmaster at the banquet, and at the close of the dinner a toast was given to the Old University, its professors and teachers, and the absent members of the class.

University of Virginia Medical Society.—A society of this name has been established by medical men residing in New York City who have studied medicine at the University of Virginia. The object is both scientific and social, and also to promote the interests of the Alma Mater. The officers are: *President*, William B. Trimble; *Secretary and Treasurer*, B. P. Riley; *Executive Committee*, W. B. Trimble, B. P. Riley, and R. G. Reese.

The Bronx Medical Association, Dr. Charles Graef, president, will hold its next meeting on Thursday evening, April 25, at 8.30 P. M. A symposium on Abortion will be followed by a general discussion. The subject will be introduced by Dr. Herman J. Boldt, A. C. Vandiver, Esq., and Dr. Charles Edward Nammack.

Cumberland County (N. J.) Medical Society.—At the annual meeting held at Millville on April 10 the following officers were elected for the ensuing year: *President*, Dr. John W. Wade of Millville; *Vice-President*, Dr. Leslie Cornwell of Bridgeton; *Secretary*, Dr. H. Garrett Miller of Millville; *Treasurer*, Dr. Joseph Tomlinson of Bridgeton.

The New York Medico-Legal Society will discuss the question of "old age, its legal responsibilities and obligations" at its regular meeting April 24, 1912, in the parlors of the Waldorf-Astoria Hotel. Papers will be read by Drs. Nascher, Crothers, Lambert, Snow, and others. The discussion will be opened by Judge Francis of Newark, Judge Platt of White Plains, N. Y., and others. The public is invited.

Hartford County (Conn.) Medical Society.—The following officers were elected at the annual meeting held in Hartford on April 2: *President*, Dr. Samuel W. Irving of New Britain; *Vice-President*, Dr. John F. Dowling of Hartford; *Secretary-Treasurer*, Dr. Paul P. Swett of Hartford.

McLean County (Ill.) Medical Society.—At the annual meeting on April 4 the following officers were elected: *President*, Dr. W. H. Gardner of Bloomington; *Vice-President*, Dr. E. B. Hart; *Secretary-Treasurer*, Dr. T. D. Cantrill of Carlock.

Miss Clara Barton, one of the organizers of the International Red Cross Society, and the founder of the American Red Cross, of which she was president for twenty-three years, died at her home in Glen Echo, Md., on April 12, in the ninety-first year of her age. Miss Barton became interested in relief work first during the Civil War when she went to the front as an army nurse, but it was in 1869, while in Switzerland that she took part in the convention which resulted in the formation of the International Red Cross, and it was largely through her representations that the United States in 1881 became a party to the international treaty guaranteeing protection to wearers of the Red Cross upon the battlefield. Appointed first president of the American Red Cross by President Garfield, Miss Barton extended the scope of the society to include, in addition to work on the battlefield, the relieving of suffering in times of great national calamity, and from the Michigan forest fires in 1881, through the famine in Texas in 1885, the earthquake in Charleston in 1886, the Johnstown flood in 1889, and the Spanish War down to the time of the tidal wave at Galveston, her activities as leader and organizer of relief through the Red Cross were unceasing. Under her management also the American Red Cross rendered valued aid in foreign countries in times of disaster, and Miss Barton had received decorations from many of the old world governments. She resigned the presidency in 1904 and had lived in retirement since that time.

Obituary Notes.—Dr. HAROLD F. JEWETT of Brooklyn, N. Y., a graduate of the Long Island College Hospital, Brooklyn, in 1893, formerly president of the Bushwick Hospital and obstetrician to the Long Island Hospital, gynecologist to the Bushwick and Swedish Hospitals, and a member of the New York State and Kings County Medical Societies, the Brooklyn Medical Society, and the Associated Physicians of Long Island, died at his home of pneumonia on April 12, aged 42 years.

Dr. M. WALLACE CULP of Union, South Carolina, a graduate of the Medical College of the State of South Carolina, Charleston, in 1881, and a member of the South Carolina State and Union County Medical Societies, died suddenly at his home on March 30, aged 55 years.

Dr. JOHN H. BRADLEY of Macon, Georgia, a graduate of the Louisville, Kentucky, Medical College in 1897, and a member of the Georgia State and Bibb County Medical Societies, died at Blue Ridge, Georgia, on March 28, aged 36 years.

Dr. OSCAR H. HALL of St. Paul, Minn., a graduate of the University of Buffalo, N. Y., Department of Medicine, in 1868, formerly president of the Minnesota State Homeopathic Society, and a member of the State Examining Board, died at his home after a lingering illness on April 2, aged 70 years.

Dr. HENRY O. WALKER of Detroit, Mich., a graduate of the Bellevue Hospital Medical College in 1867, and a member of the American Medical Association and the Michigan State and Wayne County Medical Societies, died at his home after a brief illness of pneumonia on April 5, aged 69 years.

Correspondence.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

THE QUEEN OPENS NEW CANCER CHARITY—HEART FAILURE—COST OF SMALLPOX HOSPITALS—INSTITUTE OF PHARMACOLOGY—SMOKE ABATEMENT AND COAL TROUBLES—OBITUARY.

LONDON, March 29, 1912

THE Queen drove to the Middlesex Hospital on Wednesday and opened the Barnato-Joel Cancer Charity which constitutes in effect a new cancer hospital and research institution. There are 43 beds, a home for 59 nurses, bedrooms for 20 servants, an out-patient department, operating theatre, electrical and research laboratory. The old cancer charity of this hospital has been completely remodelled, so that the two combined have 90 beds, 58 for female and 32 for male patients. All the floors, partitions and flat roofs of the new buildings are fireproof. They adjoin the older cancer department of the hospital on the west side of which they stand and are connected by corridors, subways and a garden approach. They have been erected and endowed with funds bequeathed by the late Henry J. Barnato (in memory of his brother and nephew) for cancer patients and cancer research. A gold key made for the purpose by the goldsmiths' company and bearing an inscription of the date and occasion was handed to the Queen by Prince Alexander of Tech and Her Majesty unlocked the barrier dividing the new from the old buildings and declared the new charity open. An inspection of the operating theatre and the electrical department followed. Here Dr. Lyster gave a demonstration in which the Queen evinced no little interest. The sisters' and nurses' quarters, the research block and hospital wards were also visited. Here Her Majesty showed that kindly interest in the patients she has so often evinced in hospital visits.

The special research laboratories of the Middlesex were established in 1900 and you know that much good work has been done in them. The new extension, with its complete equipment, cannot fail to give further opportunities for investigation to the zealous workers who will continue their efforts under the improved conditions.

Heart failure was the subject set for this year's annual debate at the Chelsea Medical Society, held at St. George's Hospital. Sir Clifford Allbutt undertook to open the discussion and I said to myself, now I may get an answer to the question that has puzzled me—what is heart failure? But this master in Israel had to acknowledge at the conclusion of a most able discourse that he had done little to solve the riddle set for physician and pathologist alike. But he was impressed with the idea that these two observers might help us by some correlation of their work instead of acting like scouts on the opposite side of a hedge. The simile is at least a change from the parallel lines of which we have heard so much, but though he indicated the need of co-operation he did not say how it was to be effected and the hedge is not removable. He did, however, give us most valuable criticism, some of it frankly destructive and all of it deserving of full consideration.

The physician will give you, he said, data in plenty and his opinions which are decisive, but he can neither predict heart failure nor prevent it. So the pathologist with a heart before him from a case of sudden death will confidently show us why with such a lesion it could not go on, but put be-

fore him another specimen with the same disease further developed and tell him that went on for many years and the possessor died of something else and he declines to guess at clinical conundrums. Yet mutual counsel and comparison might be advantageous.

Sir Clifford Allbutt did not dwell much on valvular diseases, as they are to some extent explicable and mechanical and do not usually end in sudden death. Dilatation is no gauge of the condition of the myocardium and the physical signs are equivocal. The syncopic phenomena which often accompany cardiac default are just as uncertain, for they are present in too many other conditions. Even the pulse is no sure guide, its variations may mean little, though two of them may be still held to be ominous. The pulsus alternans is still regarded as a herald of myocardial defect, but it is not a common feature and so an inconstant criterion. But the second variation of pulse—a permanent change of rate—is of greater import whether it be of acceleration or retardation. The tract of Tawara may be profoundly marred without affecting the pulse; a normal pulse, too, is consistent with profound impairment of the left myocardium. Yet Sir C. Allbutt declared himself strongly impressed that permanent change of rate is ominous of failing heart. Let a man, he said, whose habitual rate is known to be 70, at rest 65-70; let this later have become habitually 85-90, on slight movements rising to 100 or more, let it show no alteration under prolonged rest, *i.e.* let it never fall below 80-85, under tranquility of mind and body, then heart failure is in the offing. Moreover, if with this acceleration there be attacks of faintness or of slight dyspnea on moderate effort, the failure of the heart's' muscle is at hand. Possible nervous influences must, of course, be allowed for and so coffee, tea, tobacco, etc., which often become less easily tolerated in later life. Speaking of nerves is it by their influence that a heart in advanced disease may be so efficient as to deceive the clinical observer outright? The heart is so beset with nerves and ganglia that the harmony of the circulation must depend intimately on their integrity, though our recent interest in other points has diverted research from these nervous governors, and besides the intracardial we have the extracardial nerve structures, vagus, and bulb, not to mention those psychical influences which are supposed to possess peculiar potency. One might guess that a cardiac failure attributable to these influences may be a cortical disturbance, propagated through the vagus. Further, the vasomotor system has degrees of reinforcement or default of which we have little notion. There are probably many subtle agents which enter alone or in combination into the nice poises of life and alterations in molecular constitution invisible even to the ultramicroscope. An old rubber band to the eye showing no change displays loss of elasticity on attempting to use it—dies suddenly. There is a world within the visible of which little or nothing is known: osmoses, surface tensions, reaction potentials, viscosities, differential pressures and so on.

The expenditure on smallpox hospitals excites some attention. The asylum board has three, none of them at present with patients, but there are 128 members of the staff to keep and other expenses. During the last eight years the patients accommodated have averaged 10.3 per annum, while the cost has been £183,000. Heating and lighting one hospital last year cost £4,000. Some time ago it was proposed to replace one of the hospitals, which is a wooden structure, by fireproof materials, the highest cost of which was estimated at £12,675; the lowest £6,650. At the board's' meeting last week it was urged that this enormous expenditure ought to be stopped and they should not rebuild until after the next epidemic. The committee had reported in favor of gradually rebuilding in permanent material, and eventually it was resolved to accept this report and begin with two wards. Of course, it was better for the wards to be empty and to hold them prepared as a form of insurance was advocated. But it does seem as if they might not be to some extent utilized and that the full staff need not be kept up for all three hospitals.

The Institute of Pharmacology constitutes the second section of the new buildings in course of erection by University College. It will accommodate 100 students and consist of a lecture room, research laboratories, a room for practical work, and buildings for housing animals. The cost is estimated at £5,500, of which £5,000 has been presented by Mr. A. Carnegie. The institute will be on one side of the Institute of Physiology and on the other there is to be a similar building for anatomy. Together with the older parts of the college, the medical institute when complete will exercise a great influence in the scientific and preliminary departments of medical education and, of course, will continue closely associated with the hospital for clinical work.

An International Smoke Abatement Exhibition is being held here by a society which is devoted to the object of preventing or diminishing London's annual soot fall, estimated at 70,050 tons. At the opening luncheon Sir W. Ramsay spoke of a plan he had been thinking over of doing without coal-burning at the spot where heat was wanted. In the midst of our coal strike, of which you will have learned the facts, any such idea naturally attracts attention and it is being said in many quarters that science is sure to meet the difficulty and miners are warned that their calculation of holding up the nation may redound to their own destruction. Sir William said the ideal of things would be to burn the coal *in situ*, conduct the gas to the surface, convert the power into electricity which could be conveyed anywhere and used for heating at a much less cost than coal fires or furnaces. He told the miners they had better pause before they lost their work altogether for if the system he had sketched failed in any particular, the resources of science were by no means exhausted.

It is with sincere sorrow I have to report the death of Dr. Pennell of the Mission Hospital at Bannu Worth, West Frontier India. He was a personal friend from his student days and I have watched his career with the deepest interest. As a student at University College he carried off gold medals, eight or nine in number, and other distinctions. At the University of London he graduated B. Sc., 1886, M. B., B. S., 1890. taking the same year the diplomas of the two Royal Colleges and the Hall. The next year he proceeded to M. D. and the next took the F. R. C. S. Eng. The residential offices at his hospital he also filled with assiduity for he had all along been determined when fully equipped in every way to take up work as a medical missionary. The Church Missionary Society gladly accepted his services and chose him to establish the station at Bannu where he began in 1803, opened the hospital which has been a great success,

became the trusted friend of the wild tribes on the frontier, whose propensities toward violence he often restrained and was said to be worth more than a regiment or two to the British Government which gave him the Kaisar-i-Hind, second class in 1901 and the first class in 1910. At the request of members of his university and college a memorial service is being held this afternoon at St. Pancras Church. He died on Saturday, the 23d, aged 45, from septicemia, according to the cable message. He leaves a widow who is also M. B. and B. S., London. He wrote "Among the Wild Tribes on the Afghan Frontier" and another volume on Northern India.

Dr. W. H. Barnett of the Bannu Mission Hospital died there on the 20th, aged 32. He was a Bart-o'-man, took M. B., B. S., London, in 1905, and filled resident offices at Radcliffe Infirmary, Oxford and at Macclesfield. He entered the medical mission field and was appointed to assist Dr. Pennell who was overworked at Bannu. He proved a very valuable colleague. He married in September, 1910. In a single week the medical mission service in general and India in particular sustains the double loss of Theodore L. Pennell and William H. Barnett.

OUR LETTER FROM THE PHILIPPINES.

(Special report to the MEDICAL RECORD.)

CEBU'S WATER SUPPLY—QUININE AND MALARIA—SEGREGATION OF LEPERS—PHILIPPINE HEALTH EXHIBIT—ASSEMBLY OF PHYSICIANS AND PHARMACISTS OF THE PHILIPPINES—DELEGATE TO THE ROME CONGRESS.

MANILA, P. I., February 28, 1912.

THE rapid advance which is being made in the Philippine Islands in the matter of sanitary betterment is well illustrated by the opening, during the past week, of the new water system for the city of Cebu, which is situated in the Visayan group on an island of the same name. Cebu, in round numbers, has a population of about 40,000, and is the second city in the Philippine Islands. It is the shipping center for the islands of Negros, Bohol, Leyte and northern Mindanao, as well as for the island of Cebu. From a sanitary standpoint it is of considerable importance because dangerous communicable diseases may be widely disseminated by the extensive shipping which the port enjoys, and for the same reason it is readily susceptible to infection when the provinces with which it trades become infected. Up to the present time there has been no water available except that of a brackish variety which was obtained from shallow wells, or that which was collected in cisterns from the roofs of buildings. As the death rate from intestinal diseases has always been high in Cebu, it will be interesting to observe whether the same satisfactory reduction in the death rate will be brought about there as occurred in Manila after the introduction of the new water supply. At a distance of about 12 kilometers from Cebu, a retaining wall was built, which is capable of damming up 400,000,000 gallons of water which collects upon an uninhabited watershed. The water is then conducted in large steel pipes to a point about four kilometers from Cebu, into a settling and distributing basin, which has a capacity of 480,000 gallons. From there, it is conducted by a system of pipes to the city, and on arrival there has a pressure of about 120 pounds to the square inch. It is estimated that the consumption, at the beginning, will be, approximately, 200,000 gallons per day. The system was formally inspected by the Governor-General and other government representatives and thrown open for use with appropriate ceremonies on February 17, 1912.

In the latter part of 1909, the Bureau of Health, with a view to relieving distress and the hope of reducing the death rate from malaria in the province of Ambos Camarines, distributed gratuitously one-half million five-grain doses of quinine sulphate. It is interesting to note that the death rates from malaria before and after the quinine distribution were as follows:

1907.		1908.	
First quarter	189	First quarter	137
Second quarter	269	Second quarter	225
Third quarter	208	Third quarter	159
Fourth quarter	321	Fourth quarter	232
	987		753
1909.		**1910.**	
First quarter	168	First quarter	129
Second quarter	160	Second quarter	133
Third quarter	247	Third quarter	168
Fourth quarter	202	Fourth quarter	131
	777		561

In 1911, when there was no further gratuitous distribution of quinine, it is interesting to note that the deaths from malaria immediately following the discontinuance of the free distribution of quinine, were as follows:

1911.	
First quarter	170
Second quarter	196
Third quarter	142

which shows a decided increase over that which had obtained before. It was rather a crude experiment, and it is, of course, impossible to say whether the distribution of the quinine influenced the death rate as favorably as the figures seem to indicate, or whether it has been due to other causes operating during that time. There is no doubt, however, that an enormous amount of distress and suffering were relieved.

The collection of lepers throughout the Philippine Islands has been steadily carried on since it was first begun in 1906. During the year 1911, 1076 lepers were collected, as against 785 for 1910, 1323 for 1909 and 1554 for 1908. In view of the fact that the great majority of the cases which are encountered now are seldom far advanced, it is reasonable to infer that the cases which are being discovered now were unrecognizable, at least by clinical means, a few years ago. Practical experience in this work has shown that, even with the full cooperation of the people, many years must necessarily elapse before the disappearance of this disease among the Filipinos can be reasonably expected. It is not too much, however, to expect that from now on, owing to the great reduction in the number of human foci, that a rapid decline in the number of new cases will take place from year to year. Since the beginning of the collecting of lepers on a systematic plan, in 1906, a total of 6481 lepers have been collected. Of this number 3043 are still alive, so that, in a period of six years, the mortality has been 46.95 per cent.

During the early part of February an Exposition was held in Manila which had for its object the placing before the people the products and manufacture of all of the provinces of the Philippine Islands. The Bureau of Health took advantage of this opportunity to make a health exhibit which proved to be of considerable educational value. Samples of rice were shown in order to illustrate the kinds which would cause beriberi. There were a number of models of sanitary houses. One large model which attracted particular attention was that

showing a section of Manila before streets were cut through the congested districts. The other part showed the district as it is today, with its houses on street lines, the level above the tide, the sides of canals walled, drainage for wastes and other simple improvements so rare in oriental cities. There was a good model of an artesian well in actual operation. The mosquito exhibit was particularly instructive and the breeding of mosquitoes was actually carried out. An experienced physician was constantly in charge who could speak the various dialects and lecture on the exhibit.

From February 3rd to February 9th, the first annual meeting of the newly organized Assembly of Physicians and Pharmacists of the Philippine Islands was held. The membership is composed entirely of Filipinos. There were over 400 members in attendance. The Director of Health, Dr. Victor G. Heiser, by special invitation, read a paper entitled "Typhoid Fever in the Philippine Islands from the Sanitary Standpoint."

Dr. Vicente de Jesus has been appointed by the Governor-General to represent the Philippine Islands at the International Congress on Tuberculosis.

GREATER DETAIL OF A RECENTLY SUGGESTED METHOD FOR THE EARLIER DIAGNOSIS OF UTERINE CANCER.

To the Editor of Medical Record:

Sir:—From a hasty perusal of our notes on an earlier diagnosis of uterine cancer and the cause of cancer in general (Medical Record, May 20, Sept. 9, Sept. 30, 1911; Jan. 20, 1912), the impression is frequently gathered that the coexistence of maximum health, weight, and strength is indicative of incipient uterine cancer. Such is not the conclusion to be drawn from a careful study of the research. A woman in perfect health is by no means necessarily the victim of malignant disease; but the uterine cancer patient will have been in apparently the same state of perfect health previous to the onset of recognized symptoms.

In taking a history of a uterine cancer patient for the purpose of studying the health conditions in the incipient stage of the disease, the physician may expect to find: (1) maximum weight; (2) maximum strength; (3) best health; also (4) increased sensibility to pain, noticed in the dentist's chair, etc.; (5) an abnormal sleepiness. The patient will have found it agreeable to retire early, not from fatigue, but from sleepiness; this extra sleep will not have interfered with her sleeping soundly all night through until time to rise; she will not have been easily disturbed. She may confess to dropping off to sleep at church, or at an entertainment, or in a chair; the last, particularly right after her evening meal. She may even answer in the affirmative your question as to whether or no she has ever been *teased* for being such a sleepy-head. (6) An increasing apathy or weariness, not fatigue. Apathy about doing things or going to places. The patient in the incipient stage of uterine cancer "can, but don't want to." The woman with other uterine diseases or disorders "wants to but can't." (7) Forgetfulness; the patient will have put things away and forgotten where she put them, or will have forgotten names which she would have every reason to remember. (8) An inclination to let things go, and not to worry. An increasing carelessness. Indifference to erstwhile pleasures and casual or unnecessary duties. Procrastination.

The above mentioned symptoms of the incipient stage of uterine cancer would account for the tardy consultation of a physician by a woman afflicted with the malady. Medical journals repeatedly deplore this unconcern on the part of the patient and publish appeal after appeal for an earlier diagnosis of the disease.

In carrying on the study it is desirable, first, that the data should be collected from patients possessing at least a fair amount of intelligence; second, that histories should be taken in every case possible by the physician himself, or by an interne who is interested in his work and has a knowledge of the exact information sought. Slight, as well as severe forms of ill health must be studied, and to be advantageously studied must be supplied by patients understandingly, hence they must come from women of the upper classes. The poor woman in the lower walks of life considers she is in good health and strength as long as she is able to work and lift heavy articles. She seldom weighs herself, and hence data in regard to weight, the condition which can be most definitely determined, are unavailable. She considers childbirth hard only when it lasts a very long time or instruments are required. Data collected from women of intelligence will alone be of real value in the research. These women are usually of the upper class, and therefore private patients whom the physician will not permit anyone but himself, or assistant, to interview; all such desirable cases will be lost to the study, unless physicians and surgeons, recognizing their obligations to science, contribute to her need. Many of these patients may satisfactorily fill out their own history sheets if encouraged to take the pains and time to recall their past as accurately as possible. The blanks used in the study in question are prepared expressly for this purpose.

The progress of the disease may be divided into three stages: incipient, early, advanced. The latter stage will not be considered. In it the patient is frequently incapable of giving thorough attention to the questions on account of her nervous, weak, and painful condition; her mind has become apathetic and her memory weak. Patients in the incipient stage are not recognized as victims of the disease, hence no opportunity of interviewing them offers. Patients in the early stage are therefore the ones from whom we may hope to obtain information which may be of value in throwing some additional light upon the cause of malignant cell-proliferation.

HOW TO AVOID "TAKING COLD."

To the Editor of the Medical Record:

Sir:—Everyone "catches cold"—that means everyone at irregular intervals suffers from a simple cold to a severe pneumonia. A simple cold with acute nasal congestion is an unmitigated nuisance, while a severe pneumonia is one of the tragedies of physical life.

I believe I have found a way by which most "colds" can be conquered if fought at their birth. Some years ago a friend said to me, "when I feel a strong draught blowing on my bald head I always rub it hard—that brings the blood back, and so I avoid taking cold." Later on, I noticed that sneezing is always followed by congestion of the face, especially in those who sneeze heartily—that is "Nature's way of bringing the blood back," said

I, remembering my bald-headed friend. Acting on this principle, I have experimented sufficiently to know that "bringing the blood back" does drive away "colds," and that sneezing is Nature's way of restoring (or trying to restore) the normal circulation when a surface anemia has been caused by surface chilling.

Therefore, when the nasal mucous membrane is first congested, and one feels he is "taking cold," let him bend the body forward (as in picking up a pin from the floor and "strain" gently till the face is red, then (in the erect position) try to breathe through the partially occluded nostrils; repeat this process till the nostrils are freely open. Of course one should exercise and take hot drinks till that chilly feeling disappears, but that does not drive away the nasal congestion which so often introduces a severe cold.

This new method of avoiding "colds" by bringing on forced nasal hyperemia, and following this by patient nasal respiration till the nostrils are freely open, "sounds silly," but after three years of practical experience, I have decided to publish this brief statement.

Visceral Purpura and Angioneurotic Edema. C. F. Withington.
A Short Account of the Early History of Suprapubic Cystotomy. C. G. Cumston.
Freud's Psychology as Applied to Children. W. E. Paul.
Memorials to Oliver Fairfield Wadsworth, M.D. C. J. Blake, J. J. Putnam, and M. Standish.

Visceral Purpura and Angioneurotic Edema.—C. F. Withington states that the group of essential purpuras is usually divided into four classes: (1) simple purpura, affecting the skin; (2) purpura rheumatica, or Schoenlein's disease, involving the skin and joints; (3) Henoch's purpura, involving skin, joints, and gastrointestinal mucous membrane, and (4) purpura hemorrhagica, or morbus maculosis Werlhoffii, which is painless and characterized by hemorrhage from all mucous membranes. A sub-variety of this form is the so-called purpura fulminans. There is a group of cases in which purpura is associated with angioneurotic edema. In Henoch's purpura the cutaneous eruptions and joint swellings are followed by colic, vomiting, intestinal hemorrhage, pain, and moderate fever. The question of the operative interference with many of these cases has presented itself and has been differently answered. Obviously, if the abdominal condition is simply one of localized edema, or of purpura, it can be generally trusted, as in the cases reported by the author, to do without surgical interference. These conditions may, however, have produced other abdominal changes such as are everywhere recognized to be the proper subject for surgical operation. Especially marked among these is intussusception, which, there is reason to believe, is in many cases produced by a local edema involving a portion of the intestine which sets up violent peristalsis, so that the swollen portion of the bowel is invaginated into the portion next below, thereby producing serious obstructive symptoms. This last group of cases indicates the extreme gravity which may occasionally attach to Henoch's purpura. In the group of operative cases, some of the operations were apparently unnecessary, but on the other hand there may develop grave lesions which would have been fatal if unrelieved, and the final group of cases, in which no operation was performed, showed similar lesions which did prove fatal. These facts make it evident that the question of surgical treatment in Henoch's purpura is a very important one and, while one should probably in the majority of cases recognize that the lesion is one which will subside in the intestine, as it usually does in the skin and other mucous membranes, one is not to assume that surgical interference may not, in certain cases, be urgently and promptly required.

Freud's Psychology as Applied to Children.—W. E. Paul states that according to Freud the infant is born with latent sexual impulses of which thumb sucking or even normal sucking are manifestations. The period of child life in the Freudian psychology is largely that of the beginnings of psychic events that later develop into hysteria, obsessions, and complexes of psychoneurotic character. Not that psychanalysis always delves back in adults to the child stage, but some elements of psychical trauma always date from early life. One is reminded of the emotionality and impressionability of even very young children. Their imaginations are active and their memories retentive. Their feelings overwhelm them, and careful parents soon begin most harmfully to impose restraint and teach the child to react artificially instead of naturally. Information is withheld and mystic fancies rouse emotions with complex potentialities. Repressions are grafted on to their behavior and the children begin psychically to take on the characteristics of their environmental associations. For example, the mother's fear of a thunderstorm is instilled into the child. In a thousand ways the child is subjected to molding psychical forces beyond analysis.

Sex Mutilations in Social Therapeutics.—G. F. Lydston notes that Indiana was the first State in the Union to put the sterilization idea into actual practice, only so far as it relates to criminals. Castration, in the author's opinion, is the logical treatment for the rapist. The emasculated rapist is an object lesson for prospective sexual criminals. Individuals whose physical or moral status is such as to insure the unfitness of their prospective progeny should have the alternative of submitting to sterilization as the only condition upon which matrimony is legally permissible.

Diet in Nervous Disorders.—T. A. Williams states that among the factors that are associated with a suitable diet the most important is enjoyment of the food. It must be cooked and served appetizingly. But even this is not enough: the psychological surroundings must be favorable. Dejection or anxiety is most detrimental to proper digestion. The frequent ingestion of food is detrimental to those persons susceptible to alimentary poisoning and its nerve inadequacy. Some of the food at least should be of firm consistency, so as to demand vigorous mastication in order to stimulate salivation. This prevents the bolting of food, a habit to which nervously impulsive persons are liable. Most epileptics are benefited and many cured if, before it is too late, a diet is imposed which minimizes the work of the metabolism of proteins. Empirically, it has been known how favorable to such patients are an abundance of fruit and vegetables and a restriction of meat. But failures in the application of this diet occur unless other proteins than meat are not restricted also; and unless the fruits and vegetables are chosen for their saline quality. The chlorides of the average diet should be restricted. They are apparently harmful to those prone to epilepsy, for although the hopes aroused by the first recommendation of

their deprivation have not been realized, yet many arrests of fits have occurred under a salt-free diet. A potent cause of nervous inadequacy is arterial hypertension. The rôle of diet in producing this seems to be important. Both purins and excessive nitrogen seem to lead to the formation of pressor substances.

The Regulation of Fees.—H. Hays emphasizes the following points which the physician should keep in mind in regard to the regulation of his fees and the collecting of these fees: (1) Fees should be regulated according to the character of the work done and the time consumed in doing it. (2) There should always be a maximum fee for the rich patient which can be scaled down to nothing for the poor patient. (3) The high cost of living should make one aware that it is time that the size of this maximum fee should be made higher, so that the physician's income will be commensurate with increased expenditures. (4) The family physician or general practitioner should receive more consideration than he does at present from his patients in regard to payment for the work he performs.

Pubiotomy.—A. Rongy believes that pubiotomy has a definite field in neglected cases of labor or cases that have been misjudged. In these cases pubic section will meet the indications when cesarean section is ruled out. When the mother and baby are in good condition and the chances for infection are not likely, although in the obstetrical sense the case is not a clean one; in such cases a competent surgeon should perform pubiotomy in the interest of the child.

Alcohol and Spirit of Camphor as Surgical Dressings.—B. Robinson recommends as a local application for wounds, bruises, sprains, etc., alcohol, or spirit of camphor and water in the proportion of one part alcohol or spirit of camphor to three parts of water. The alcohol may even be applied pure. On open wounds one or the other is preferable to bichloride of mercury or any other antiseptic.

The Surgery of Bones.—J. B. Murphy states that the periosteum, when fully detached from the bone and transplanted into a fatty or muscle tissue bed in the same individual, may, in a young person, produce a lasting bone deposit, but this rarely occurs if transplanted into another individual of the same species and not at all in another species. Periosteal strips raised at one end from the bone, if turned out into muscle or fat, regularly produce bone on their under surface for the greater portion of their length. Transplanted into other individuals and brought into contact at one end with exposed or freshened bone, such periosteum rarely produces new bone even to a slight extent. Bone with its periosteum transplanted into muscle, fat, etc., in the same individual without bone contact practically always dies and is absorbed, except in the very young. In another species it is always absorbed. Bone transplanted without the periosteum always dies and is absorbed in the muscular or cellular tissue, but with or without periosteum and in contact with other living bone at one or both ends it forms a scaffolding for the reproduction of new bone, though the transplanted fragment itself is always absorbed. Bone covered at the ends by cartilage and on the sides by periosteum, even when in touch with living bone denuded of periosteum, dies and is absorbed. When the graft is covered with periosteum at the point of contact with living bone regeneration fails, but if the periosteum of the gratt is split up into shreds regeneration may take place. The indications for bone transplantation are to correct deformities resulting from defective development; to produce union in ununited fractures; to replace bone removed by destructive infections; to restore or supplant bone tissue dislodged or destroyed by fractures; and to replace bone removed for non-malignant neoplasms, and bone removed for encapsulated malignant diseases, such as sarcoma.

Therapeutic Use of Citric Acid.—H. B. Hemenway calls attention to the therapeutic use of citric acid and the citrates in conditions due to excessive viscosity of the blood. The condition of brawny swelling thus produced is relieved by the citric acid reducing the viscosity, bringing fresh leucocytes into action, and helping the gorged and crowded ones out of the way. Viscosity of the blood is due to its colloid constituents and is distinct from coagulability. While they may be coincident they are independent and one may be high while the other is low. The obstructed circulation from viscosity favors thrombosis.

Chronic Constipation.—A. C. Reed states that a peculiar form of constipation is due to spasmodic contraction which occurs in lead poisoning and in neurasthenic and melancholic individuals. Belladona is the best antispasmodic for these cases and oil enemata are also useful Chronic habitual constipation, however, is mainly of two types—first, loss of normal irritability or motile irritability, and, second, loss of normal stimulus. The first of these may be due to an abnormality in the mucosa, musculature, or nervous mechanism. Lesions of the mucous membrane occur in chronic intestinal catarrh and in atrophy of the mucosa, which may of itself be an independent infection. Peritoneal inflammation can also involve the intestinal muscle and paralyze it. Muscular insufficiency without inflammation calls for stimulating tonic treatment. Decreased normal stimulation of the intestine is largely due to an overconcentrated food supply and diet, lacking in substances that exercise a mild irritant action, such as are found in the indigestible parts of the food, such as coarse vegetable fibers.

Pain in the Upper Abdomen.—J. Daland states that pain in this region is usually due to gallstones or to duodenal or gastric ulcer. Pain due to uncomplicated gallstones comes and goes suddenly, without warning, at intervals of hours, days, months, or years. Gallstones may, however, exist in the gall bladder without symptoms. The pain and its duration and intensity depend on the size and position of the calculus and the amount of obstruction that it can produce. Slight attacks may occur from swelling of the ducts, masses of mucus, or overdistention. A friction fremitus heard over the gall bladder containing gallstones has been described. In suppurative cholangitis, diffused dull pain in the hepatic region with local tenderness and daily intermittent fever, simulating malaria, may occur. Adhesions may be produced causing obstruction and pain. The pain of biliary colic may be simulated by hyperchlorhydria or hyperacidity, or both. Chronic ulcer of the stomach causes burning, boring or gnawing pains, relieved by food and drink or alkalies and recurring two to five hours after meals. The attacks may persist for weeks, followed by intervals lasting for months or years. Hematemesis and

melena are important signs of gastric ulcer, but their absence is not of diagnostic importance. Chronic indurative or indolent gastric ulcer usually occurs in the pyloric region and is marked by the long interval of comparative good health between the attacks which masks the diagnosis and leads to a belief in a cure. The ulcer is, however, most dangerous and should receive surgical treatment. Medical treatment is only palliative. The pyloric region is a favorite site of ulcer and cancer. Chronic duodenal ulcer is more common than the gastric form and seems to occur more frequently in males. It presents the same difficulties of diagnosis and dangers of prognosis as pyloric ulcer and requires the same prompt surgical treatment. Duodenal kinking may cause pain like ulcer and a radiograph will reveal the condition. Gastric carcinoma in more than half of the cases starts on the site of an ulcer. It may be painless even in advanced cases and its detection may be easy, difficult, or impossible.

The Lancet.

March 30, 1912.

Meat Poisoning.—F. A. Bainbridge states that *B. suipestifer* and *B. enteritidis* (Gaertner) are rarely found in the healthy human alimentary canal. Their usual habitat is the intestine of certain of the lower animals: *B. suipestifer* occurs chiefly in pigs and at times in mice, whereas *B. enteritidis* (Gaertner) is found frequently in rats, occasionally in cattle, and rarely in other animals. In outbreaks of meat poisoning caused by *B. suipestifer* the meat has usually become infected after death; in the majority of cases it is derived from pigs. Intravital infection also occurs. In outbreaks caused by Gaertner's bacillus the meat has frequently been obtained from animals which were ill when slaughtered. In some cases the contamination of the meat doubtless occurs after death. In sixteen out of twenty-four outbreaks the meat was derived from cattle. There is but little evidence that ptomaines play any important part in meat poisoning; the majority of the outbreaks are due to meat infected either with Gaertner's bacillus or with *B. suipestifer*.

Classification in Gynecology.—W. E. Fothergill presents the following classification of gynecological affections: Developmental errors, vascular changes, mechanical lesions, results of infection, progressive conditions, and retrogressive conditions. Developmental errors must, for gynecological purposes, contain two sub-groups: (*a*) congenital errors, and (*b*) errors in development at puberty, for the reproductive organs have two phases of development, one embryonic and fetal, the other occupying the year immediately preceding and following puberty. Vascular changes include active and passive hyperemia as recognized at first by symptoms and later by hypertrophy and fibrosis respectively. This group also includes varicosity of the veins in the pelvis and hemorrhage into the pelvic organs, the pelvic cellular tissue, and the peritoneal cavity. Mechanical lesions form a large and obvious group containing injuries, displacements, and hernia. Results of infection should be subdivided according to the organisms present in each case. In this group the few cases of primary pelvic parasitic disease may be included without impropriety. Progressive conditions include overgrowths, cysts, and new growths. Perhaps this group should be divided. But it is hard to draw the line between hypertrophy and adenoma of the endometrium or between innocent and malignant new growths. Retrogressive conditions occur mainly in connection with the menopause, but the reproductive organs share in the general changes of senility.

Postural Treatment of Abscess of the Lung and Liver.—W. E. McKechnie reports the case of a boy fourteen years old who had coughed up pus to the extent of a teacupful daily for five years. From the character of the pus, the practically aseptic condition, and the physical signs, the author diagnosed liver abscess with perforation of the diaphragm and pleura and secondary abscess in the base of the lung, with adhesion of lung, liver, and pleura to the diaphragm in the neighborhood of the perforation; with intermittent partial evacuation of the cavities in the liver and lung via the bronchi and trachea. The author made the boy hang suspended over the edge of a table, head downward, the whole body hanging vertically upside down, the legs and thighs lying on the table at right angles to the body and thus supporting him. In this position he was made to cough. The result was efficient evacuation of the abscess cavity. This treatment was carried out five or six times daily and at the end of six weeks resulted in a complete cure.

Pulmonary Embolism Following Diphtheria.—D. Stewart reports the case of a girl aged four years who was admitted to the hospital with mild faucial diphtheria, and progressed favorably until after a fortnight's residence in hospital, when she became moderately feverish and very restless, and presented signs and symptoms pointing to pulmonary trouble. Alteration of the respiratory murmur was made out over the right upper lobe, though from the increasing restlessness examination was difficult. Pneumonia was provisionally diagnosed, but the child grew very rapidly worse, with increasing lividity, restlessness, and respiratory embarrassment. Death took place within twenty-four hours of the first appearance of symptoms. Noteworthy points in the case were the mildness of the primary angina and the suddenness of the onset of the fatal sequel, the pulse rate rising from 108 to 140, and the respiratory rate from 24 to 40 in an hour. Also the temperature was not raised proportionately to the pulse and respiration rates. These points and the quick fatal issue combined to make the author doubt the accuracy of the provisional diagnosis, especially as thorough auscultation had been impossible. At postmortem examination a large infarction implicating the upper right lobe was found. Some dilatation of the right side of the heart was present, but no gross valvular lesion.

British Medical Journal.

March 23, 1912.

Heart Failure.—Sir T. Clifford Allbut discusses the extreme difficulties which confront the clinician and pathologist in trying to discover in any given case the causes of heart failure or in seeking some method by means of which impending heart failure may be recognized. In no organ is this lack of concord between the signals of life and death so disconcerting as in the heart. In all living structures there is a factor of safety, that potential which in the heart we call reserve, but in none, perhaps, is it so capacious as in the heart. Yet of this reserve, of what the heart can do in case of need, we have no scientific measure; the microscopist cannot detect it, the clinician has no valid tests for it. The author knows of no evidence

that mere hypertrophy depends upon any encroachment on the normal reserves of the heart. So far as evidence yet goes, an hypertrophied myocardium is as good as a normal muscle. Dilatation is no gauge of the histological condition of the myocardium; in some cases, as in acute rheumatism for instance, an impaired ventricle may be attended with dilatation; in others, as for instance in diphtheria, no such correlation may be found. A fagged or anemic patient may without any grave affection of the heart nevertheless present for a while the defects of impulse and the quality of sounds which in another might truly signify such a flaw. These equivocal physical signs, then, are not criterions. Syncopic or vertiginous phenomena often accompany cardiac default; but, whether from dyspepsia, slight labyrinthine disturbance, vasomotor atony, or other obscure cause, we are too familiar with this kind of symptom to rely upon it as crucial in the diagnosis of failing heart. It has been asserted again and again that the profounder changes in the myocardium are betrayed by an irregular pulse; but as experience of cardiac disease has widened we have learned that in the rhythms we have rarely any criterion of cardiac values. In another way the pulse may signify decay of the myocardium—namely, by a persistent change of rate, whether of acceleration or of retardation; though here, again, we have not a constant but an inconstant criterion. Of the many other and more familiar symptoms of heart failure, such as dyspnea, slight edema, slight albuminuria, cyanosis of ears and lips, fullness and tenderness of the liver, pulmonary crepitations, arrhythmia perpetua, the author states that more or less sudden heart failure is frequent without any of these features; and in any case they usually signify late phases of the malady. Sphygmomanometrical observations have as yet proved to be of no use in the detection of myocardial disease. The part which the nerves play in cardiac function is very obscure. Besides the intracardial nervous structures there are also the extracardial, the vagus and the bulb; not to mention those psychical influences which on the heart are supposed to have a peculiar potency. Again, the vasomotor system has degrees of reinforcement or default of which we have little notion. One should also remember the chances of sudden death by fat embolism, nerve toxins, pulmonary embolisms, and so forth; or possibly, by increases of the specific gravity of the red corpuscles. Then there is the world of chemical reactions in the heart; the ionic motions and substitutional interchanges of which we know little.

The Estimation of Heart Power.—W. Russell states that in taking hemomanometer observations three factors of clinical importance have to be considered, namely, (1) blood pressure; (2) structural changes in the wall of the artery; and (3) hypertonus of the muscular coat. Upon the correctness of one's estimate of these separate factors will depend the correctness of one's conclusions, and will determine the real value of this instrument in clinical work. There is no escape from the exercise of discretion and judgment when using this instrument; the significance and value of each point have to be determined in every case.

Berliner klinische Wochenscrift.

March 11, 1912.

"Vital Staining" and Chemotherapy.—Schuleman announces the results of some experiments on the relationship between tinctorial quality and therapeutic effects. The selective action of stains may imply selective therapeutic effects. Staining is believed to indicate that a chemical reaction occurs between the coloring matter and the protoplasm. The entire problem of the relationship between chemical constitution and physiological action is naturally here involved. The author endeavored to vary the molecule of trypan blue. This contains numerous side chains of known therapeutic efficacy—hydroxylons, amido groups, methyl groups, etc. The coloring matter benzopurpurin which is devoid of hydroxyl groups was tested for control, as were also other principles which contained no amido and methyl groups respectively. It appeared that these side chains did not confer the desired properties on the molecule. Varying the sulfonic acid groups was also without effect. The tinctorial quality did not depend on the size of the molecule. The author had to abandon for the time being the molecular constitution of the stain. How does the staining principle get inside the cell? It cannot dissolve the lipoids of the cell membrane. It may, however, be in a peculiar state of colloidal division, in virtue of which it passes between the fat particles. The azo and sulfonic acid groups are believed to stand in direct relationship with the colloidal properties, the presence of hydroxyl and amido groups being much less significant in this respect. In studying simple mineral dyes points of analogy may be seen. The stain does not seem to depend absolutely on the chemical constitution, but rather on the so-called chromophore group, and the latter owes its activity to some physicochemical property such as ability to form certain colloidal suspensions. If the author's conclusion is just, there is nothing therein to oppose Ehrlich's chemotherapeutic teachings, but a new element should be superadded to the latter.

Diagnostic Value of the Leucocyte Inclusions in Scarlet Fever.—Kretschmer refers to an article on this subject by Döhle, who in thirty cases of scarlet fever of various stage and intensity found inclusions in the polynuclears. They are naturally at a maximum during the leucocytosis at the onset of the disease, and begin to vanish by the end of a week, persisting for a variable interval, which may amount to four weeks or more. There is evidently no connection between this phenomenon and later developments, for it does not reappear with relapses and complications. There is no claim made as to specificity, for Döhle found the inclusions in other miscellaneous conditions, in which there is no constancy of incidence. The author has studied the phenomenon in nonscarlatinal conditions and in the healthy; and in seventy of the most heterogeneous cases found the inclusions in four, or about 6 per cent. There is therefore a presumption at the outset that the phenomenon has to do with the *Streptococcus pyogenes*, and, as a matter of fact, this view was borne out in every one of the positive finds. On the other hand the author has not only found the inclusions in all the scarlatina cases investigated by him, but was even able to recognize the existence of the disease in an exposed child before it was seized by the latter. Moreover, he has excluded scarlatina in the early days of acute angina, Vincent's angina, and diphtheria. The author has been able to pick out the inclusion cases in nonlabeled specimens. Several stains may be used, but the author prefers the so-called Manson's procedure, in which methylene blue is used. The inclusions are about the size of ordinary cocci.

Nature of Mouse Tumors.—Apolant, representing Prof. Ehrlich, announces that the mouse tumors are veritable cancers despite all assertions to the contrary. It is conceded, however, that notable biological differences exist between these growths and human cancer, which may be sufficient to negative the prodigious efforts of the past decade in seeking a line of rational treatment for the latter affection. Wassermann has stated that he is now able to produce the disappearance of mouse tumors by chemotherapeutic methods, and it is, of course, highly desirable that we have no illusions in respect to analogous power over human cancer. The argument at present seems to revolve about the analogies between mouse tumors and human cancer of the breast. The author states that the former are histologically typical mammary cancers, while von Hansemann holds the opposite view.

Insurance Medicine.

SUGGESTIONS TO MEDICAL EXAMINERS.

BY THE INSURANCE EDITOR.

THE PHYSICAL EXAMINATION.

OBESITY AN ABNORMAL CONDITION.—The expression "fat and healthy" is familiar and also misleading but believed in by laymen who are usually at a loss to understand why some ruddy, corpulent individual is refused as a risk or offered a policy on a different plan than the one applied for. The prevalent idea that fat serves as a reserve fund to draw upon in the case of emergency or illness is easily disposed of when studying the wide experience of life insurance companies. And yet obesity has not always been regarded as an indication of health, for far back in the early part of the seventeenth century Francis Bacon came near to the truth in his History of Life and Death, when he wrote that "fatness in youth pointed to a short span of life."

In obesity, as in other morbid conditions, a given exciting cause has a more injurious effect in some individuals than in others. Thus, some persons however much they eat or drink never become fat, while in the case of others everything taken turns to fat though they have not particularly good appetites and are not indolent. The defective state of the metabolic functions which, in association with a *relative* excess of food, leads to obesity, may be due not only to hereditary influences, want of exercise and habitual disturbance of the metabolic functions from alcoholic drinks, but also occasionally to incidental causes which are sometimes only transient. For instance obesity often follows typhoid and other fevers and accompanies certain nervous conditions and disorders of the sexual organs.

Causes of Death	Over weights	Under weights	Combined Experience

TABLE OF DISEASES PECULIAR TO OVERWEIGHTS AND UNDERWEIGHTS.—In order to ascertain the causes from which overweights and underweights die, Dr. Brandreth Symonds (MEDICAL RECORD, September 5, 1908) studied the death claims of 1,499 overweights and 1,078 underweights taken from the records of the company he represents. The figures obtained are compared with the entire mortality in the same company in the following table, and will serve to illustrate the remarks appearing in these columns on the subjects of overweights and underweights, as it gives quite a good idea of the malign influence at work in these cases. The figures represent the percentage of deaths from different diseases, those in the first and second columns referring to overweights and underweights and those in the third to the general experience of the company as set forth in its mortality statistics from 1843 to 1898.

EFFECTS OF OBESITY ON LONGEVITY.—By referring to the table in the section on "Maximum and Minimum Weights" in a previous number giving the percentage of mortality in overweights, it is seen that the mortality rises rapidly among moderate and excessive overweights as the age advances. Up to the age of about 29 overweight seems to indicate a certain hypernutrition and robustness that is favorable to subsequent life. This is indicated by the figures given, from which it may be concluded that overweight in an individual below 29 years of age is not harmful even up to 30 or 35 per cent. above the standard, provided the weight does not increase with advancing years. This holds good for the actual weight, not the relative weight, for the standard increases with advancing age; so that an excess of 33 per cent. at age 22 is practically the same as 20 per cent. at age 45 and the subject in such a case has, therefore, just succeeded in keeping out of the undesirable class of overweights. After the age of 29 overweight universally shortens life irrespective of sex or nationality to a marked degree, the mortality running as high as 160 per cent., a most excessive rate and one which no company conducted on safe and conservative lines can afford to allow. A slightly better mortality is exhibited in the table for persons between 57 and 70 years of age than for those between 43 and 56. This is probably due to more care in the selection of elderly risks.

For very good reasons, then, no good insurance office will accept an individual at ordinary rates, if at all, whose weight bears more than a certain proportion to his height, for it is notorious that such persons bear accidents badly and succumb to illnesses that would be much more often survived by healthy subjects. Furthermore, it is agreed among those who have given any study to the subject that these risks are poor not only because they are in an abnormal condition, less able to withstand shock and seldom reach an advanced age, but also for the reason that they are particularly prone to develop Bright's, heart disease, arteriosclerosis, apoplexy, diabetes, and cirrhosis of the liver.

OVERWEIGHT WITH EXCESSIVE ABDOMINAL MEASUREMENT.—These are particularly bad cases as a class. Rejection of the risk is the only safe plan to pursue when the abdominal measurement comes within a half inch or exceeds that of the expanded chest, both taken on the bare skin in accordance with the suggestions already offered in these columns. The increase in mortality in these cases is 10 to 15 per cent. over heavy weights without excessive abdominal measurement, and runs even higher when the abdominal measurement greatly exceeds that of the expanded chest.

OVERWEIGHT AND TUBERCULOSIS TENDENCY.—The mortality of overweights is not so poor when there are long lived family histories, those in which neither parent has died below the age of 70. While that of the young overweight remains good, as expected, the gain is sufficient in mature moderate overweights to keep the mortality well below 100 per cent. In all other classes, however, the mortality remains bad.

If the family history is an average or short lived

one, the mortality will be increased. Under these circumstances the young moderate overweights still retain a fairly good mortality, but the young excessive overweights show mortality increased to about 100 per cent. The other classes are rendered just so much worse.

A tuberculous family history seems to have about the same effect as a short lived family history. In the young it certainly has no worse effect and, on the whole, it may be said that overweight tends to counterbalance the predisposition to tuberculosis to such a marked degree that the amount of fatal tuberculosis in these cases is less than one-quarter of that which is found in general experience and hardly one-sixth of that occurring among underweights.

Life Insurance in India.—A paper was read on the above subject at a recent meeting of the Life Assurance Medical Officers' Association of London by Adrian Caddy. The records were commenced by Coulton and Arnold Caddy in 1892, and since Coulton's retirement in 1904 Adrian Caddy has assisted his brother in their compilation. The paper read by Caddy is really a lengthy and exhaustive report, entering into somewhat minute details of all questions bearing on the matter. According to the author the differences between cases in India seem much more trivial than in Europe. The population of India is about 300 millions, of whom about 100 millions are in Bengal, Eastern Bengal, and Behar. Most of the work referred to in the paper has been with the Bengali race and its neighbors; thus it may be considered that the figures deal chiefly with about one-third of the population of India.

As for height and weight of Europeans in India it appears that below 5 feet 6 inches the average weight is above the normal, and over 5 feet 6 inches the average weight is less than normal. This may be ascribed to the influence of medical selection before arrival in India, or it may be put down to the more active and open-air life enjoyed in India; exercise improving the physique of persons under weight and tending to diminish obesity in the stout. Contrary to general belief the average native weight corresponds very closely to the European standard. The average height of Indians was found to be 65.85 inches, while the average height of Europeans examined come to 67.95 inches. The following table shows the percentage of each group that were either declined or were insured at a higher premium:

Disease	Europeans (1,799)	Bengalis (3,483)
Inferior physique..	1.55 per cent.	5.36 per cent.
Obesity	2.11 "	5.34 "
Glycosuria	.61 "	3.24 "
Albuminuria	1.22 "	1.98 "
Consumption	.44 "	.91 "
Consumptive family history	1.38 "	.77 "
Bad family history.	.5 "	.93 "
Syphilis	1.0 "	.34 "
Heart disease.....	1.05 "	.86 "
Sundry diseases...	3.39 "	4.06 "
Elephantiasis	.... "	.22 "
Alcoholism	.72 "	.22 "

The vast majority of the natives of India are believers in vaccination or inoculation, and the remainder have generally had smallpox. Hydrocele is fairly common among the Bengalis. The general conclusions arrived at are in the main as follows: The European does not acclimatize in the tropics, that is to say, he is not able to rear healthy, strong children in India, and he is not able to continue for a long period in the same state of health as he was on arrival in the country. Quite apart from the effects of tropical diseases, the European gets debilitated by residence in the tropics, and at least every four or five years requires a change to a temperate climate. The children of Europeans who have been sent home when four or five years old for their education are generally not so fine physically as their parents. The chief proof that the European does not acclimatize in the tropics is his inability to withstand the tropical sun without any head covering.

Summarizing the various points of the paper the author thinks that he has shown:

1. The native of India is usually a shorter man than the European.

2. Height for height, the native weighs the same on an average as the European; there is no evidence to show that his tissues are any lighter than those of a European.

3. The native is very subject to glycosuria, due probably to his carbohydrate diet.

4. He is subject to hydrocele, the reason for which is not evident.

5. Opium and hemp drugs are not commonly consumed by the insuring classes.

6. The author thinks that it will be proved in the future that the use of these drugs is not so innocuous as has been believed.

Cripple Insurance.—Rokotnitz proposes a system of insurance which would diminish the economic loss caused by the existence in society of crippled persons. His scheme provides for the payment for most advanced medical and surgical procedures which offer hope of diminishing the disability caused by the crippling lesion. In case this is impossible he proposes an insurance which would make up for diminution of earning power in case of the birth of a cripple in a family. He thinks that such insurance can be well combined with the usual life and accident insurance.—*Zeitschrift für die gesammte Versicherungs-Wissenschaft*, March 1, 1912.

Mortality in Various Trades.—From an exhaustive study of the mortality among bookbinding trades in Vienna Dr. S. Rosenfeld concludes that even apparently related trades may show quite dissimilar mortality figures, not only in relation to total death rate, but likewise in relation to the death rate for certain specific diseases. It is, therefore, inaccurate to gather many related trades together in studying mortality rates. These differences are due to very small differences in the circumstances and environment of the different artisans. In the study of mortality among trades as many subdivisions must therefore be made as possible, and detailed figures obtained. Moreover, increased mortality from some one disease must not be necessarily explained by the trade circumstances, but may be due to some quite extraneous and subtle factors. Moreover, only relative and not absolute figures give a correct conception of mortality, and therefore mortality figures in a trade in one town cannot be fairly compared with such figures in another town; other elements of population in the same town should be taken for comparison.—*Wiener klinische Wochenschrift*, February 1, 1912.

State Medical Licensing Boards.

STATE BOARD EXAMINATION QUESTIONS

BOARD OF MEDICAL EXAMINERS OF MARYLAND

December 12-15, 1911.

ANATOMY.

1. Describe the occipital bone.
2. Name the carpal bones.
3. Name varieties of articulations—give example of each.
4. Give origin and distribution of great sciatic nerve.
5. Give origin, insertion, and nerve supply of quadratus lumborum, brachialis anticus, orbicularis palpebrarum and sartorius.
6. Describe the epithelium of the pharynx.
7. What glands are in the small intestines and where located.
8. Describe a villus. What is its function?
9. What arteries form the circle of Willis?
10. What and where is the pituitary body?

PHYSIOLOGY.

1. What is meant by the physiological effect of a drug?
2. Into what general classes are foods divided? (*b*) Give examples of each.
3. What effect has starvation upon the proteins?
4. What is animal heat? (*b*) What relation exists between the temperature of the body and the pulse? (*c*) What is the difference between warm and cold blooded animals?
5. What is meant by nerve cells and nerve fibers? (*b*) Define afferent, efferent, trophic, inhibitory, motor, and vasomotor nerve fibers.
6. What is meant by diffusion and osmosis?
7. What is meant by absorption and nutrition?
8. Which organs of the body secrete and which excrete?
9. Describe the method of producing artificial respiration?
10. What is the composition of: Saliva, gastric juice, blood, and urine?

MATERIA MEDICA.

1. Iodine; how obtained. (*b*) The official preparations.
2. What is black wash? Yellow wash? (*b*) What are wines? (*c*) What is the difference in the preparation of lozenges, tablets, and triturates? Name some of the official lozenges.
3. What is the difference between anesthetics and anodynes? Name some of each most generally used? (*b*) What is the difference between liniments and lotions? Name some of the official.
4. Give the average dose of tincture of aconite, tincture of nux vomica, tincture of digitalis, tincture of opium, tincture of veratrum.
5. To what class of drugs does bismuth belong? What are the official preparations and doses?
6. What is the difference between irritants and counter-irritants? Name the most important.
7. Name six preparations of iron and their doses. (*b*) What are the incompatibles of iron?
8. Write a prescription containing: Iron, arsenic, strychnine, and quinine, using the official terms and state when best administered.
9. Write a prescription containing: Tincture of aconite, sweet spirit of niter, spirit of Mindererus, using the official terms.
10. Silver: its official preparations and doses. What are the incompatibles of silver?

THERAPEUTICS.

1. Give therapeutics of hypodermoclysis and method of administration.
2. Write a prescription in Latin, without abbreviation, containing four ingredients which you would use for an acute bronchitis and give directions for using same.
3. Write a prescription in Latin, without abbreviation, containing three ingredients which you would use for diarrhea and give directions for using same.
4. Give the therapeutics of eserine and usual method of administration.
5. Give therapeutic uses of three zinc salts and name antidotes for zinc poisoning.
6. Name the official preparations of oxygen and give their therapeutic uses.
7. Give the therapeutics of three preparations of ammonium and name them.
8. What is meant by a "gastric tonic" or "stomachic?" Give indications for use and mode of action.
9. Give the therapeutics of H_2O, hot and cold.
10. Give the physiological action and therapeutics of aconitum.

CHEMISTRY.

1. Define: (*a*) reagents; (*b*) valence; (*c*) crystalloid, (*d*) colloid; and (*e*) atom.
2. Give the chemical name and composition of "laughing gas," how it is obtained, and what are its properties?
3. Give one chemical antidote for each of the following: (*a*) antimony; (*b*) lead acetate; (*c*) cocaine; (*d*) morphine; and (*e*) phenol.
4. Describe in detail the examination of a sample of urine for the detections of bile, sugar, and albumin.
5. (*a*) What are metals? (*b*) What are nonmetals? (*c*) What are amalgams? and (*d*) What are indicators?
6. Give the chemical formula of each of the following: (*a*) Nitric acid; (*b*) boric acid; (*c*) sodium bromide; (*d*) zinc oxide; and (*e*) calomel.
7. What is glycerine? What is its source in nature? How is it obtained and what are its properties?
8. (*a*) What is an alcohol; (*b*) what is an alkaloid; (*c*) what is a salt; and (*d*) what is a hydrocarbon?
9. Give the "Law of constancy of composition."
10. Complete the following equation:

$NH_3 + HCl =$
$MgO + H_2SO_4 =$
$2KOH + H_2SO_4 =$
$NaOH + HCl =$
$Na_3PO_4 + 3AgNO_3 =$

PATHOLOGY.

1. Ascaris lumbricoides; describe briefly life cycle and characteristics; mention two or more dangerous conditions brought about by infection with this parasite.
2. Mention at least four varieties of ulceration seen in the gastrointestinal wall. Describe the gross appearance of an amebic ulcer.
3. What are the dangers inherent to diseased tonsils?
4. What is meant by active congestion? Passive congestion? Give an example of each.
5. Trace the probable course of events which follow chronic obstruction of the urethra.
6. Given a slide supposed to be smeared with gonorrheal pus: How would you proceed to establish the fact?
7. On what principle does vaccination against typhoid fever depend? How is the vaccine prepared?
8. Describe the process of repair in an uninfected fracture of bone.
9. Describe the exudate in a pneumonic lung in the stage of red hepatization.
10. Define, explain, and give examples of exudate and transudate.

PRACTICE.

1. Define: (*a*) Von Graefe's sign, (*b*) uremia, (*c*) arteriosclerosis, (*d*) cirrhosis of the liver, (*e*) angina pectoris.
2. Define: (*a*) dysphagia, (*b*) hematuria, (*c*) hemoptysis, (*d*) laryngismus stridulus, (*e*) pertussis.
3. What diseases most commonly occur in the right inguinal region?
4. Differentiate neuritis and rheumatism.
5. Differentiate diphtheria and acute follicular tonsillitis.
6. Differentiate rubella, rubeola, and scarlatina.
7. Differentiate intestinal colic, uterine colic, and renal colic.
8. Give treatment of angina pectoris.
9. Give treatment of lobar pneumonia.
10. Give treatment of acute dysentery.

OBSTETRICS.

1. Name the sutures of the fetal head.
2. What precautions should be taken against septic infection during labor?
3. Indications for use of forceps and mode of application.
4. What are the objections to the use of ergot and stimulants in labor?
5. How would you prevent perineal tears during labor and delivery?
6. What are the varieties of placenta prævia?
7. Outline the care of the navel.
8. Describe some of the best substitutes for mother's milk.
9. What are the different forms of endometritis?
10. Mention the varieties of vaginitis and their treatment.

SURGERY.

1. Name the varieties of fractures of vault of cranium. Prognosis and treatment.

2. Name the different varieties of fractures, their etiology, symptoms, and complications.

3. Give a classification of dislocations with the etiology, predisposing cause, and anatomic peculiarity of each.

4. Give indications for operative treatment of fractures.

5. Give the early diagnosis of exophthalmic goiter.

6. Differentiate between obstruction of common and cystic ducts.

7. Describe glaucoma: Give signs and treatment.

8. Define hematoma, aneurysm, thrombus, and embolus.

9. Indications and contraindications for salvarsan in treatment of syphilis. Technique of your method of administration.

10. Causes and treatment of acute otalgia

ANSWERS TO STATE BOARD EXAMINATION QUESTIONS.

BOARD OF MEDICAL EXAMINERS OF MARYLAND.

December 12-15, 1911.

ANATOMY.

1. See Cunningham's Anatomy (1900), page 108; or Gray's Anatomy (1910), page 70.

2. *The carpal bones* are arranged in two rows, those of the upper row (enumerated from the radial to the ulnar side), are: Scaphoid, semilunar, cuneiform, and pisiform; those of the lower row (enumerated similarly) are: Trapezium, trapezoid, os magnum, and unciform.

3. VARIETIES OF ARTICULATION. 1. *Diarthrodial*, or freely movable; as hip and knee. 2. *Amphiarthrodial*, or slightly movable; as symphysis pubis and joints between bodies of vertebræ. 3. *Synarthrodial*, or immovable; as ethmoid with vomer and parietal with frontal.

4. *The great sciatic nerve* arises from the sacral plexus, and passes out of the pelvis through the great sacrosciatic foramen, below the pyriformis muscle; it extends down the back of the thigh, passing between the great trochanter of the femur and the tuberosity of the ischium; at the lower third of the thigh it divides into the internal and external popliteal nerves. It supplies the hip-joint and the biceps, semitendinosus, semimembranosus, and adductor magnus *muscles*.

5. QUADRATUS LUMBORUM. *Origin*: From iliolumbar ligament, crest of ilium, and transverse processes of three or four lower lumbar vertebræ. *Insertion*: Into lower border of twelfth rib and transverse processes of four upper lumbar vertebræ. *Nerve supply*: Anterior branches of lumbar nerves. BRACHIALIS ANTICUS. *Origin*: Lower half of outer and inner surfaces of the shaft of the humerus, covering insertion of the Deltoid, and intermuscular septa. *Insertion*: Rough depression on the anterior surface of the coronoid process of the ulna. *Nerve supply*: Musculocutaneous and musculospiral.

ORBICULARIS PALPEBRARUM. *Origin*: Internal angular process of frontal bone, from frontal process of superior maxillary bone, and from tendo oculi. *Insertion*: It surrounds the orbit. *Nerve supply*: Facial nerve.

SARTORIUS. *Origin*: Anterior superior spine of ilium, and part of notch below. *Insertion*: Inner side of tibia near tubercle. *Nerve supply*: Middle cutaneous, or branch from anterior crural.

6. See Cunningham's Anatomy (1909), page 1037; or Gray's Anatomy (1910), page 1233.

7. See Cunningham's Anatomy (1909), page 1061; or Gray's Anatomy (1910), page 1290.

8. See Cunningham's Anatomy (1909), page 1062; or Gray's Anatomy (1910), page 1292.

The function of a villus is to absorb the digested food.

9. The *Circle of Willis* is formed: In front by the two anterior cerebral arteries (branches of the internal carotid), which are connected by the anterior communicating artery; behind, by the two posterior cerebrals (branches of the basilar artery), which are connected to the internal carotid on each side by the posterior communicating artery.

10. The pituitary body is a ductless gland consisting of two distinct portions which differ in structure and also in function. It is situated on the sella turcica of the sphenoid bone.

PHYSIOLOGY.

1. By the *physiological effect* of a drug is meant the effect that the drug exerts upon the various bodily organs or tissues in health.

2. *Foods are divided into*:

I. Inorganic { Water. / Salts.

II. Organic { Non nitrogenous { Carbohydrates / Fats. / Nitrogenous Proteins.

Examples of each: *Carbohydrate*, sugar and starches; *Fat*, fat of meat, and butter; *Protein*, flesh of animals, and white of eggs; *Salt* sodium chloride, and calcium phosphate.

3. *Effect of Starvation on the proteids*. At first the body lives on the proteids derived from previous food; then on the proteids of the tissues. The nitrogen excreted rapidly falls in amount, and soon reaches a minimum. When the fat of the animal has been used up, there is a rise in the nitrogen excreted, and this is followed by a rapid fall, as death approaches.

It is believed that the proteids (during starvation) pass into solution in the blood and are thus used to nourish the body and to supply the heat necessary to maintain the body temperature.

4. *Animal heat* is the heat produced in living organisms by the processes of oxidation. Normally a body temperature of 98° F. corresponds to a pulse of 60; 99° F. to a pulse of 70; and in most cases a rise of 1° F. is attended by an increase of 8 to 10 pulse beats per minute.

Warm-blooded animals are such as have a fairly constant body temperature independently of the temperature of the medium in which they live.

Cold-blooded animals are such as have a body temperature which varies according to that of the medium in which they live.

5. *A nerve cell* is the cell body of a neuron.

A *nerve fiber* is a process of a nerve cell, which conducts impulses.

An *afferent nerve* is one that conveys impulses from the periphery to the brain (or the center).

An *efferent nerve* is one that conveys impulses from the brain (or the center) to the periphery.

A *trophic nerve* is one that conveys efferent impulses which govern the nutrition of some organ or tissue.

An *inhibitory nerve* is one that conveys efferent impulses which restrain or inhibit the action of some organ.

A *motor nerve* is one that conveys efferent impulses to muscles, thus causing and regulating their contraction.

A *vasomotor nerve* is one that conveys efferent impulses to the muscular tissue of blood vessels, thus regulating the amount of blood conveyed to a part.

6. "The term *diffusion* has long been applied to the regular mixing of the molecules of two gases when brought into contact in a confined space. More recently it has been applied to the mixing of the molecules of two solutions when brought into contact. If, however, the two solutions are separated by a membrane, permeable to the solutions, diffusion will still occur. To this form of diffusion the term *Osmosis* has been applied in the case of water, and *Dialysis* in the case of diffusible substances. All bodies can be divided into two groups, *crystalloids* and *colloids*. To the former group belong bodies having a crystalline form, which readily go into solution in water. All such bodies are diffusible (dialyzable), their power of dialysis, however, varying considerably. To the second group belong such bodies as have no crystalline form (amorphous). These are generally bodies with a large molecule, which form colloidal suspensions in water, and are only slightly or not at all diffusible. An exception to this second group is hemoglobin, which has a very large molecule but is crystalline and is diffusible"—(Kirkes' *Physiology*.)

7. *Absorption* is the process by which the products of digestion are conveyed to the circulation. *Nutrition* is the sum of the processes by which the body digests, absorbs, and assimilates suitable materials brought into contact with it.

8. (*a*) *Structures of excretion*: Lungs, kidneys, intestines, skin. (*b*) *Structures of secretion*: Serous and synovial membranes; mucous membranes (glands in mouth, stomach, and intestines); salivary glands and pancreas; liver; mammary glands; lacrymal glands; kidneys; skin; testes.

9. See Rose and Carless' Surgery (1911), page 949; or Da Costa's Surgery (1911), page 1106.

10. *Saliva* consists of water and solids (mucin, ptyalin, a protein, potassium thiocyanate, sodium chloride, sodium carbonate, calcium phosphate, calcium carbonate, magnesium phosphate, potassium chloride.

Gastric juice contains: Water, pepsin, rennin, hydrochloric acid, chlorides (of calcium, sodium, and potas-

sium), and phosphates (of calcium, magnesium, and iron).

Blood is composed of plasma and corpuscles. The *plasma* consists of water and solids (proteids, extractives, and inorganic salts). The *red corpuscles* consist of water and solids (hemoglobin, proteids, fat, and morganic salts).

The *white corpuscles* consist of water and solids (proteids, nuclein, lecithin, histon, etc.).

Urine is composed of: Water; urea, uric acid, urates, hippuric acid, kreatin, kreatinin, xanthin, hypoxanthin, sulphates, chlorides, and phosphates of sodium and potassium; phosphates of magnesium and calcium; nitrogen, and carbon dioxide.

MATERIA MEDICA.

1. *Iodine* is obtained from the ashes of sea weed or kelp. Kelp contains iodine in the form of sodium iodide. This is treated with sulphuric acid and distilled with manganese dioxide:

$$2NaI + 2H_2SO_4 + MnO_2 = MnSO_4 + Na_2SO_4 + 2H_2O + I_2$$

The *official preparations of iodine* are: The tincture, the compound solution, and the ointment.

2. *Black wash* is a lotion containing calomel in lime water.

Yellow wash is a lotion containing corrosive sublimate in lime water.

Wines are liquid preparations containing the soluble principles of medicinal substances dissolved in wine.

Lozenges contain mucilage of tragacanth or adhesive paste.

In *tablets* the adhesion of the particles is due to the use of a volatile liquid like alcohol.

In *tablets* the basis is generally powdered sugar.

In *triturations* the basis is sugar of milk.

Official lozenges: Troches of tannic acid, of ammonium chloride, of cubeb, of gambir, of glycyrrhiza and opium, of krameria, of potassium chlorate, of santonin, and of sodium bicarbonate.

3. *Anesthetics* destroy sensation; *anodynes* relieve pain by depressing the centers of sensation in the cerebrum or by impairing the conductivity of sensory nerves. The *anesthetics destroy* sensation (for a time); *anodynes diminish* sensation.

Anesthetics: Ether, chloroform, nitrous oxide, ethyl chloride, cocaine, eucaine, ice.

Anodynes: Opium, morphine, cannabis indica, acetanilid, aconite, veratrin, phenol, chloral hydrate.

Liniments are solutions of medicinal agents in oily liquids or in alcoholic liquids containing fatty oils.

Lotions contain medicinal agents, usually in water, with (sometimes) alcohol or glycerin.

Official liniments: Linimentum ammoniæ, L. belladonnæ, L. Calcis, L. camphoræ, L. chloroform, L. saponis, L. saponis mollis, and L. terebinthinæ.

There are no official lotions.

4. AVERAGE DOSE: Tincture of aconite, 10 minims; tincture of nux vomica, 10 minims; tincture of digitalis, 15 minims; tincture of opium, 8 minims; tincture of veratrum, 15 minims.

5. *Bismuth* is classed as an astringent.

The official preparations (with doses) are: The citrate, dose 2 grains; bismuth and ammonium citrate, 2 grains; the subcarbonate, 7½ grains; the subgallate, 4 grains; the subnitrate, 7½ grains; and the subsalicylate, 4 grains.

6. *Irritants* are substances which, when applied to the skin, produce vascular excitement; when used to produce a reflex influence on some part remote from the site of their application they are called *counterirritants. The chief are:* Mustard, capsicum, chloroform, iodine, oil of turpentine, croton oil, cantharides.

7. *Six preparations of iron, with their doses:* Reduced iron, 1 grain; ferrous sulphate, 3 grains; pills of ferrous carbonate, 2 pills; tincture of ferric chloride, 8 minims; Basham's mixture, 4 drams; pyrophosphate of iron, 4 grains.

Incompatibles: Acids, acid salts, alkalies and their carbonates, and vegetable astringents.

8. ℞. Arseni trioxidi, gr. ss.
Strychninæ sulphatis, gr. j.
Ferri reducti, ℈ss.
Quininæ bisulphatis, ℈j. M.
Fiat massa in pilulas no. xxx dividenda.
Sig: Take one after each meal.

9. ℞. Tincturæ aconiti, ℥iij.
Spiritus ætheris nitrosi, ʒiij.
Liquoris ammonii acetatis, q.s. ad ʒvj. M.
Sig: Take two teaspoonfuls in water every three hours.

10. SILVER. *Official preparations and doses:* The nitrate, dose 1/5 grain; the oxide, 1 grain; and the cyanide, moulded nitrate, and mitigated nitrated, which are not taken internally.

Incompatibles "Incompatible with the *nitrate* are: Acetates, alkalies, alcohol, antimony salts, arsenites, bromides, carbonates, chlorides, chromates, creosote, cyanides, copper salts, ferrous sulphate, glucose, hypophosphites, iodides, morphine salts, oils, manganous salts, organic substances, phosphates, sulphides, sulphates, tartrates, vegetable astringent infusions and decoctions. Incompatible with the *oxide* are: Antimony and arsenic sulphides, salts of bismuth, copper, iron and mercury, creosote, iodine, organic substances, phosphorus, tannic acid."—(Potter's *Materia Medica*, etc.)

THERAPEUTICS.

1. "Hypodermoclysis is a method of supplying fluid to the body to replace that lost through excessive purging, as in cholera, or in cases of hemorrhage. Further, it may be used to wash from the body various impurities circulating in the blood and lymph, and to flush the kidneys. In other instances it may be used to supply the body with liquid when the stomach will not permit liquid to be swallowed, as in vomiting, or gastric ulcer, or after abdominal operations. It consists in the introduction into the subcutaneous tissue of normal saline solution, which is rapidly absorbed by the vessels.

"When hypodermoclysis is employed after hemorrhage the results are often extraordinary. It is of great value in the collapse of cholera. The cyanosis decreases rapidly, the pulse improves, and respiration is no longer difficult. Some physicians have used hypodermoclysis with very good results in the treatment of uremia, and it is believed that not only are the poisons washed out of the system by this method, but, in addition, that the dilution of the poisons prevents them from acting so severely. In septicemia, diabetic coma, and similar states this method of treatment should be employed and the results carefully recorded. When general dropsy is present it is manifestly useless. Hypodermoclysis has also been used with great advantage in the treatment of severe burns to overcome shock and toxemia. In cases of surgical shock warm saline fluid used by hypodermoclysis is often of great service."—(Hare's *Therapeutics.*)

For *method of administration* see Rose and Carless' "Surgery" (1911), page 280; or Da Costa's "Surgery" (1911), page 265.

2. ℞. Ammonii carbonatis, ʒj.
Spiritus chloroformi, ʒj.
Syrupi pruni virginianæ, ʒj.
Misturæ glycyrrhizæ compositæ, q.s. ad ʒviij. Misce.
Signa: One tablespoonful every three hours.

3. ℞. Acidi hydrochlorici diluti, ℥iij.
Tincturæ nucis vomicæ, ℥iij.
Tincturæ gentianæ compositæ, q.s. ad ʒiij. Misce.
Signa: One teaspoonful in water three times a day, after meals.

4. *Eserine* causes increase of saliva and of perspiration; increased peristalsis; it increases and then diminishes blood pressure and heart action; it causes the pupil to contract; and depresses the nervous system. It is used in flatulence, dilatation of stomach or intestines, tetanus, epilepsy, chorea, respiratory troubles, and as an antidote in strychnine poisoning.

It is used largely in ophthalmic practice. "In a solution of gr. ij to the ounce of water dropped into the eye it is efficient in breaking up or preventing adhesions of the iris, diminishes intraocular tension, prevents suppuration after operations, contracts the pupil, diminishing the entrance of light in photophobia, and empties the vessels of the eye. It is very useful in keratitis, glaucoma, strumous ophthalmia, and neuralgia of the eyeball."—(Potter.)

5. *Therapeutics of zinc salts:* "The sulphate and acetate are used as astringent injections and applications in gonorrhea, leucorrhea, gleet, otitis, conjunctivitis, etc., and the others, in powder or ointment, are employed in a great variety of conditions where a mild astringent effect is desired. The ointment of zinc oxide is perhaps more widely used than any other in the treatment of acute skin diseases. Internally the sulphate is a serviceable emetic in narcotic and other poisoning, and it and the oxide are used in digestive derangements, diarrhea, dysentery, etc. The oxide has been given for the night sweats of phthisis and in various nervous diseases."—(Wilcox's *Materia Medica.*)

Antidote for zinc poisoning: The stomach should be washed out; then milk, white of eggs, or tea, or infusion of bark should be given; then the stomach should be washed out again.

6. The official preparations of oxygen are: Water and solution of hydrogen dioxide.

For *water*, see below, QUESTION 9.

"*Hydrogen dioxide*, in fresh solution, is one of the most powerful oxidizing agents known, by reason of the facility with which it parts with oxygen to oxidizable substances brought in contact with it. It is consequently a powerful yet non-toxic antiseptic, destroying morbid products and organized ferments to which it is applied. In contact with a suppurating surface it generates a white foam, as the result of its action on the pus. This soon subsides, leaving the subadjacent tissue cleansed of all morbid secretions. One part added to 1000 of water containing sewage or infectious microbes is sufficient to destroy the various organisms if allowed to act thereon for twenty-four hours."—(Potter's *Materia Medica.*)

7. *Ammonium carbonate* is used as a cardiac and gastric stimulant, also as an expectorant, and in the cure of alcoholism.

Ammonium chloride is used as an expectorant, in neuralgias, hepatic disorders, rheumatism, and alcoholism; externally it is used in inflammatory conditions of mucous membranes.

Solution of ammonium acetate is used as a diaphoretic and diuretic in fevers, chronic nephritis, dropsy, and alcoholism.

8. *Stomachics or gastric tonics* "are agents which increase the appetite and promote gastric digestion. They include a number of substances, dietetic and medicinal, some acting by stimulating the production of gastric juice, others by stimulating the local circulation, and several by exciting the activity of the nervomuscular apparatus of the stomach. The first indication is met by the use of dilute alkaline solutions before meals; the second by administering any of the pungent carminatives, as the aromatic oils, pepper, mustard, etc., or by alcohol and ether in small doses, or by the aromatic bitters, as gentian, orange, etc., or the simple bitters, as calumba; while the third desideratum is secured by the use of such agents as nux vomica, hydrastis, arsenic, the dilute mineral acids, and the volatile oils."—(Potter's *Materia Medica.*)

9. *Therapeutics of water:* "Cold baths are employed in the treatment of febrile diseases, more particularly typhoid fever. It is important that frictions should be maintained all the time the patient is in the water. Various modifications of the full cold bath are also employed. Ice-water baths are of great service in sunstroke or thermic fever, and cold water may be injected into the bowel when the skin is cold but the central temperature high. Large injections of cold water are also useful in dysentery. Ice bags are sometimes applied to various parts of the body for the purpose of controlling inflammatory action and also for the hemostatic effect of the cold. Warm baths are employed to soothe pain, alleviate muscular and mental fatigue, promote sleep, and relieve spasmodic conditions and internal congestion. Hot baths and the hot pack are useful in renal disease and uremia, and in commencing colds, on account of the free diaphoresis they induce. Localized hot baths aid in the same way as general ones, but are less pronounced in their effects. In various painful affections of the eye much relief may be afforded by the application of hot water on cotton pledgets frequently renewed, or by allowing the water to drop continuously on the eye. Internally water is of great service in keeping the urine diluted, and its free use tends to prevent the formation of gallstones, as well as of gravel or urinary calculi. A glass or two of water swallowed upon rising often has the effect of causing an evacuation of the bowels. Tepid water, sometimes with the addition of mustard, is very commonly used as an emetic.—(Wilcox's *Materia Medica.*)

10. ACONITE. *Therapeutics:* For fevers, some inflammatory conditions, in high arterial tension, in nervous palpitation of the heart, and congestive dysmenorrhea; also externally for neuralgia, pruritus, herpes, chilblains, etc. *Physiological action:* First stimulates and then paralyzes heart and also sensory nerves; lowers blood pressure; dilates peripheral blood-vessels, is a respiratory sedative; reduces body temperature; is a diuretic and diaphoretic.

CHEMISTRY.

1. *Reagent* is an agent used in making a chemical reaction.

Valence is the combining power of an atom of an element as compared with that of an atom of hydrogen.

Crystalloid is a substance which when in solution can pass through an animal membrane.

Colloid is a substance which when in solution cannot pass through an animal membrane.

Atom is the smallest part of an element which can enter into chemical action, or that can enter into the composition of a molecule.

2. *Laughing gas* is nitrogen monoxide, N_2O. Its molecule is composed of two atoms of nitrogen and one atom of oxygen. It is obtained by heating ammonium nitrate:

$$(NH_4)NO_3 + \text{heat} = 2H_2O + N_2O.$$

It is a colorless, odorless gas with a sweetish taste, heavier than air, moderately soluble in water and in alcohol; when inhaled it produces exhilaration, loss of consciousness, and anesthesia.

3. *Chemical antidote:* For antimony, tannic acid; for lead acetate, magnesium sulphate; for cocaine, amyl nitrite; for morphine, caffein; for phenol, alcohol.

4. First of all, test for the *albumin*, as follows: The urine must be perfectly clear. If not so, it is to be filtered, and, if this does not render it transparent, it is to be treated with a few drops of magnesia mixture, and again filtered. The reaction is then observed. If it be acid the urine is simply heated to near the boiling point. If the urine be neutral or alkaline it is rendered *faintly* acid by the addition of dilute acetic acid, and heated. If albumin be present a coagulum is formed, varying in quantity from a faint cloudiness to entire solidification, according to the quantity of albumin present. The coagulum is not redissolved upon the addition of HNO_3.

If albumin is present it should be removed. The urine is then tested for *sugar* and for *bile*, as follows. For *sugar:* Render the urine strongly alkaline by addition of Na_2CO_3. Divide about 6 c.c. of the alkaline liquid in two test tubes. To one test tube add a very minute quantity of powdered subnitrate of bismuth, to the other as much powdered litharge. Boil the contents of both tubes. The presence of glucose is indicated by a dark or black color of the bismuth powder, the litharge retaining its natural color.

Test for *bile:* Put 3 c.c. HNO_3 in a test tube, add a piece of wood, and heat until the acid is yellow; cool. When cold, float some of the urine to be tested upon the surface of the acid. A green band is formed at the junction of the liquids, which gradually rises, and is succeeded from below by blue, reddish-violet, and yellow.

5. A *metal* is an element which is capable of replacing the hydrogen of an acid to form a salt.

A *non-metal* is an element other than a metal.

An *amalgam* is a substance composed of mercury and some other metal or metals.

An *indicator* is a substance used in chemical analysis to show the completion of a chemical reaction.

6. Nitric acid, HNO_3; boric acid, H_3BO_3; sodium bromide, NaBr; zinc oxide, ZnO; calomel, Hg_2Cl_2.

7. Glycerine is a triatomic alcohol with the formula $C_3H_5(OH)_3$. Its source in nature is from palm oil and other vegetable oils. It is obtained by the saponification of fats by boiling with sodium hydroxide:

$$\underset{\text{Glyceryl oleate}}{C_3H_5(C_{18}H_{33}O_2)_3} + 3NaOH = \underset{\text{Sodium oleate}}{3NaC_{18}H_{33}O_2} + \underset{\text{Glycerin}}{C_3H_5(OH)_3}$$

Glycerin is a colorless, viscid liquid, with a sweet taste; its reaction is neutral, and it mixes readily with water.

8. An *alcohol* is the hydroxide of a hydrocarbon radicle, which reacts with acids to form esters.

An *alkaloid* is a basic, nitrogenous, organic substance of alkaline reaction and capable of uniting with acids to form salts in the same way that ammonia does.

A *salt* is a substance formed by the substitution of a basylous or electropositive element (or radicle) for part or all of the replaceable hydrogen of an acid.

A *hydrocarbon* is a substance which contains carbon and hydrogen only.

9. *The law of constant proportions:* The same compound always contains the same elements and in the same proportions.

10. $NH_3 + HCl = NH_4Cl$

$MgO + H_2SO_4 = MgSO_4 + H_2O$

$2KOH + H_2SO_4 = K_2SO_4 + H_2O$

$NaOH + HCl = NaCl + H_2O$

$Na_3PO_4 + 3AgNO_3 = Ag_3PO_4 + 3NaNO_3$

PATHOLOGY.

1. See French's "Practice of Medicine" (1910), page 509; or Osler's "Practice of Medicine" (1909), page 38.

2. See French's "Practice of Medicine" (1910), pages 794 and 255; or Osler's "Practice of Medicine" (1909), pages 501, 470, and 3.

3. Diseased tonsils may give rise to: Laryngitis, cervical cellulitis, quinsy, suppuration or hypertrophy of tonsils, mouth breathing, adenoids, rheumatism, endocarditis, phlebitis, diphtheria, tuberculosis, or other infection.

4. In *active congestion* there is an increase in the quantity of arterial blood in the part affected, with distention of the capillaries. The condition is one of active hyperemia.

In *passive congestion* there is an increase in the amount of venous blood in the part affected; there is faulty exit of the blood, with retarded flow.

Active congestion is seen in inflammation.

Passive congestion is seen in the swollen finger produced by tying a moderately tight band around it.

5. See Rose and Carless' "Surgery" (1911), page 1202; or Da Costa's "Surgery" (1911), page 1359.

6. To demonstrate *gonococci:* On a cover-glass make a smear with the discharge as thin as possible, and let it dry in the air; cover it with a freshly made solution of anilin-oil-gentian-violet for one or two minutes; wash it in distilled water; leave it in Gram's solution for two minutes; wash it in 95 per cent. alcohol until decolorized; wash it in distilled water; counterstain with a dilute carbolfuchsin without heat, or with a saturated aqueous solution of Bismark brown; wash in distilled water, dry with filter paper, mount, and examine with an oil-immersion lens. The gonococci will appear as *diplococci within the leucocytes,* which have been *decolorized by Gram's stain,* and have taken the counterstain.

7. The object of vaccine therapy is to produce an active immunity, and to bring about an increased bacterial destruction with the liberation of an increased amount of endotoxin. As a result of inoculation with vaccines there may be found antitoxins, antiendotoxins, lysins, agglutinins, precipitins, opsonins, and other allied products. Wright prepares the typhoid vaccines from 24-hour cultures grown upon the surface of agar, and, after emulsification, standardized to contain 1,000 millions of typhoid bacilli in every cubic centimeter. Sterilization is effected by heating for half an hour at 56° to 58° C., and ½ per cent. lysol is afterwards added. The dose is 500 or 1,000 millions of bacilli.

8. See Rose and Carless' "Surgery" (1911), page 471; or Da Costa's "Surgery" (1911), page 528.

9. See French's "Practice of Medicine" (1910), page 155; or Osler's "Practice of Medicine" (1909), page 170.

10. "In health the so-called serous cavities of the body contain very little fluid. In pathological conditions large accumulations of fluid may be observed, not only in the serous cavities, but also in the areolar connective tissue, beneath the skin, and beneath the muscles. When due to circulatory disturbances or a hydremic condition of the blood such accumulations of fluid are spoken of as *transudates;* while the term *exudates* is applied to similar accumulations of inflammatory origin. Clinically it is frequently difficult to distinguish between transudates and exudates.

"*Transudates* are usually serous in character, when they present a light straw color; at times, however, owing to admixture of blood, they have a reddish tinge, and are then said to be hemorrhagic; in rare instances they are colorless.

"*Exudates* may be serous, serofibrinous, hemorrhagic, seropurulent, purulent, putrid, chylous, or chyloid. Of these the seropurulent, purulent, and putrid types are manifestly of inflammatory origin; while in the case of the serous, serofibrinous, and hemorrhagic forms it may at times be difficult to determine whether the fluid represents a transudate or whether it is an exudate."—(From Simon's *Clinical Diagnosis.*)

PRACTICE.

1. *Von Graefe's sign:* The upper eyelid does not follow promptly the downward movement of the eyeball; found in exophthalmic goiter.

Uremia: A form of autointoxication occurring in some cases of nephritis and in anuria.

Arteriosclerosis: A thickening and hardening of an artery due to a fibrous overgrowth of the intima and degenerative changes in the middle coat of the artery; the artery loses its elasticity and contractility.

Cirrhosis of the liver: A condition in which the parenchymatous cells of the liver are atrophied or degenerated, while the interstitial connective tissue is hypertrophied.

Angina pectoris: A severe constricting pain in the thorax radiating from the heart down the left arm, sometimes into the back, and accompanied by a severe cardiac oppression and a fear of impending death.

2. *Dysphagia:* Difficulty in swallowing.

Hematuria: Passage of blood in the urine.

Hemoptysis: Hemorrhage from the lungs or bronchial tubes.

Laryngysmus stridulus: A spasmodic closure of the glottis, lasting a few seconds and followed by a noisy inspiration.

Pertussis: Whooping cough; an acute infectious disease characterized by recurrent and spasmodic attacks of coughing followed by a deep and noisy inspiration.

3. *Diseases most commonly occurring in the right inguinal region:* Appendicitis, inguinal hernia, fibroid tumors, hematoma, pyosalpinx, ovarian cyst or abscess, psoas abscess, foreign bodies, floating kidney, and cancer of cecum.

4. See French's "Practice of Medicine" (1910), pages 1012, 1014, 225, and 228; or Osler's "Practice of Medicine" (1909), pages 909, 1003, 225, and 395.

5. In *diphtheria* the onset is more gradual; the temperature rises to about 102° to 103° F.; the tonsils are not much enlarged; there is an exudate of a thick, grayish membrane which is very adherent, is removed only with difficulty, and leaves a bleeding surface; this membrane soon re-forms and may be found on the fauces and pharynx as well as on the tonsils; in the exudate the Klebs-Loeffler bacilli may be found. In *follicular tonsillitis* the onset is more sudden; the temperature may be a little higher than that of diphtheria; there is no membrane, but the tonsils are red and swollen, and in the crypts are seen white, cheesy spots or plugs, which consist of broken-down epithelium and are easily brushed away; Klebs-Loeffler bacilli are never found.

6. *Scarlatina:* Period of incubation, from a few hours to seven days. Stage of invasion, twenty-four hours. Character of eruption, a scarlet punctuate rash, beginning on neck and chest, then covering face and body; desquamation is scaly or in flakes. The eruption is brighter, is on a red background, punctiform, and is more uniform; the temperature is higher, the pulse quicker; the tongue is of the "strawberry" type; the lymphatics in the neck may be swollen, and there is sore throat; Koplik's spots are absent. *Rubeola:* Period of incubation ten to twelve days. Stage of invasion, four days. Character of eruption, small, dark red papules with crescentic borders, beginning on face and rapidly spreading over the entire body; desquamation is branny. The eruption is darker, less uniform, more shotty; the temperature is lower, pulse slower, the tongue is not of the "strawberry" type; coryza, coughing, and sneezing may be present; Koplik's spots are present. *Rubella:* Period of incubation ten to seventeen days. Stage of invasion, one day. Eruption appears on first day, is most intense on second day, consists of red papules, often fades from face before it is seen on the limbs. The pulse is not much accelerated, all the symptoms are slight. Desquamation is very slight. There may be slight sore throat and swollen cervical glands. Koplik's spots are absent.

7. *In renal colic:* The pain is in the region of the affected kidney, it radiates down the thigh; there are intense rigors; retraction of the testicle may be present; also history of previous attacks or of calculi; the urine may be scanty, suppressed, or bloody.

In intestinal colic: The pain is generally around the umbilicus; the abdomen is tympanitic; there are no rigors; there may be a history of indiscretion in diet.

In uterine colic: The pain is in the pelvis, and is associated with menstrual disorders; in fact, it is a dysmenorrhea.

8. See French's "Practice of Medicine" (1910), page 637; or Osler's "Practice of Medicine" (1909), page 842.

9. See French's "Practice of Medicine" (1910), page 171; or Osler's "Practice of Medicine" (1909), page 189.

10. See French's "Practice of Medicine" (1910), page 258; or Osler's "Practice of Medicine" (1909), pages 6 and 246.

OBSTETRICS.

1. See Jellett's "Midwifery" (1910), page 113; or Hirst's "Obstetrics" (1909), page 394.

2. See Jellett's "Midwifery" (1910), page 148; or Hirst's "Obstetrics" (1909), pages 732, etc.

3. See Jellett's "Midwifery" (1910), pages 1031, 1033, etc.; or Hirst's "Obstetrics" (1909), pages 809 and 811.

4. *The use of ergot:* "The routine administration of ergot after the birth of the child is not to be recommended. No remedy should be administered in any condition unless there is a direct indication for its use. In primipara and strong multipara the uterine contraction should be strong enough to effectually empty the cavity of the womb and obliterate the venous channels. In such cases the ergot is useless or even dangerous in that it may cause an irregular hour-glass contraction of the uterus, with retention of clots, membranes, and débris, and at the same time has a retarding influence upon the development of the milk. Then again, if given before the birth of the child, serious or even fatal asphyxia may result from the tetanic contractions induced by the drug. The danger of laceration of the cervix, perineum, and vaginal wall as well as of rupture of the uterus is increased by the use of ergot. There is, however, a suitable class of cases in which the use of ergot is indicated in appro-

priate doses. This includes all forms of uterine exhaustion and inertia during the late second and third stage and after delivery has been completed."—(Dorland's *Obstetrics.*)

5. See Jellett's "Midwifery" (1910), page 344; or Hirst's "Obstetrics" (1909), page 335.

6. See Jellett's "Midwifery" (1910), page 714; or Hirst's "Obstetrics" (1909), page 574.

7. See Jellett's "Midwifery" (1910), page 1145; or Hirst's "Obstetrics" (1909), pages 345 and 377.

8. See Jellett's "Midwifery" (1910), page 1154, etc.; or Hirst's "Obstetrics" (1909), page 928, etc.

9. *Forms of endometritis:* Acute and chronic; congestive, gonorrheal, tubercular, septic, senile, decidual. (There is no recognized classification.)

10. *Forms of vaginitis:* Superficial, simple, granular, senile, emphysematous, bacterial (such as gonorrheal diphtheritic, tuberculous, syphilitic, chancroidal). (There is no recognized classification.) *Treatment* consists in rest, cleanliness, douches, the application of soothing lotions, and removal of any cause; salines and anodynes are also indicated.

SURGERY.

1. See Rose and Carless' "Surgery" (1910), pages 744, 748, 749, and 752; or Da Costa's "Surgery" (1910), pages 807 and 808.

2. See Rose and Carless' "Surgery" (1910), pages 405, 470, 478, and 481; or Da Costa's "Surgery" (1910), pages 517 to 528.

3. See Rose and Carless' "Surgery" (1910), page 611, etc.; or Da Costa's "Surgery" (1910), page 664, etc.

4. *Operative Treatment of Simple Fractures:* "In certain cases it is found impossible to bring the fragments into accurate apposition or to retain them there. This may be due to the obliquity of the fracture, as, for example, in the bones of the leg; to the interlocking of fragments, as occurs frequently in epiphysial separations; to the traction of powerful muscles on one of the fragments, as in fracture of the patella or olecranon; or to the interposition of soft tissues between the broken ends. Under such circumstances it may be necessary to expose the fracture by operation, and after reducing it to fix the fragments together by wires, pegs, staples, or screws. Operative interference is usually delayed till about a week after the injury, by which time the effect of other measures will have been estimated, and accurate information obtained by means of the *x*-rays regarding the nature of the lesion and the position of the fragments. Such operations, however, are not to be undertaken lightly, as they are difficult, and if septic infection takes place the results may be disastrous. Arbuthnot Lane advocates a more general resort to operative measures, even in simple and uncomplicated fractures."—(Thomson and Miles' *Surgery.*)

5. See Rose and Carless' "Surgery" (1910), page 1008; or Da Costa's "Surgery" (1910), page 1235; or French's "Practice of Medicine" (1910), page 558; or Osler's "Practice of Medicine" (1909), page 766.

6. See Rose and Carless' "Surgery" (1910), page 1076; or Da Costa's "Surgery" (1910), pages 1034 and 1035.

7. *Glaucoma* is a diseased condition of the eye, produced by increased intraocular pressure, and resulting in excavation and atrophy of the optic disc, and blindness. It is due to increase of the contents of the eye, hypersecretion, retention, old age, gout, rheumatism, nephritis. *Symptoms:* Visual disturbances, increased ocular tension, hazy and anesthetic cornea, sluggish and dilated pupil, shallow anterior chamber, ciliary neuralgia, cupping of optic disc, blindness. *Treatment:* Myotics, such as eserine or pilocarpine, massage of the eyeball; mydriatics are contraindicated; operative treatment may include paracentesis, iridectomy, or sclerotomy.

8. *Hematoma:* A blood tumor, or circumscribed hemorrhage with the blood lying in a distinct cavity in the tissues.

Aneurysm: A pulsating sac containing blood and communicating with the lumen of an artery.

Thrombus: A blood clot formed in the heart or a blood-vessel during life, and remaining at its point of formation.

Embolus: A similar clot, but brought from a distance and plugging up a blood-vessel.

9. *Salvarsan is indicated* in: "(*a*) Early cases of syphilis in which contagious manifestations are appearing in rapid succession, in spite of efficient mercurial medication. (*b*) Cases in which, for family or social reasons, it is of special importance to limit the production of infective material or cause the disappearance of symptoms in the shortest possible time. (*c*) Cases in which the symptoms are recalcitrant to the action of mercury, or in which, from idiosyncrasy, that drug cannot be exhibited in sufficient dose. (*d*) Cases of syphilophobia and syphilomania, whether showing symptoms or not; its psychic action in these instances being of greater importance than its therapeutic effect. (*e*) Very early cases of the sequelæ of the luetic infection, before organic changes have occurred."

Salvarsan is contraindicated in: "(*a*) Cases that are doing well, *i.e.* in which the disease is pursuing its normal mild course under ordinary medication. (*b*) Cases with serious organic lesions of the eyes, kidneys, heart, or other internal organs. (*c*) Cases with postsyphilitic or parasyphilitic disease of the internal organs, more especially of the nervous system."—(*Progressive Medicine.*)

For *method of administration* see Rose and Carless' "Surgery" (1911), page 159.

10. Otalgia is earache. *Earache* may be due to a wide variety of causes—in the meatus, cerumen, furuncle, or dermatitis; in the middle ear, acute catarrh, or suppuration, acute or chronic. It may be referred from a carious tooth, or from disease of the tongue, or may be due to Eustachian obstruction secondary to pharyngitis and frequently to adenoids. For a satisfactory treatment a correct diagnosis is essential; and, if possible, the cause must be removed.

To relieve the pain: Apply dry heat; or drop into the external meatus a few minims of equal parts of tincture of aconite and tincture of opium; or similarly apply ten drops of a 2 per cent. solution of phenol; or spray over the tympanic membrane a 4 per cent solution of cocaine, and force a little of the same into the Eustachian tubes by letting the patient inhale the spray, and then expanding the tubes by Valsalva's method; this repeated every three minutes is said to be a sure method of cure.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, Held March 25, 1912.

DR. CHARLES GILMORE KERLEY IN THE CHAIR.

Bills in the Assembly.—Dr. E. ELIOT HARRIS, Chairman of Committee on Legislation, read an act introduced by Mr. MacGregor, read once and referred to the Committee on Judiciary. This was an Act to incorporate the Doctor J. H. Dye Medical Institute. The objects of this corporation were the manufacturing, compounding, and vending of medicines and medical and medicinal preparations, consultations and prescribing, consultations and operations in surgery, etc. This corporation might advertise its compounds, preparations, and medicines, its manner of treatment, and the fact that it had in its employ and maintained physicians and surgeons who would consult with and prescribe for patients. The amount of the capital stock of said corporation shall be $100,000 and the existence of said corporation shall be perpetual.

Dr. Harris read an Act introduced by Mr. Bush, read once and referred to the Committee on Public Health. This was in relation to amending the public health law regarding operations for the prevention of procreation. Immediately after the passage of this Act the Governor shall appoint one surgeon, one neurologist, and one practitioner of medicine, each with at least ten years' experience in the actual practise of his profession, for a term of five years, to be known as the board of examiners of feeble-minded, criminals, and other defectives. If in the judgment of the majority of said board procreation by such persons would produce children with an inherited tendency to crime, insanity, feeble-mindedness, idiocy, or imbecility and there was no possibility that any such person so examined would improve to such an extent as to render procreation by the person advisable, the said board should appoint one of its members to perform such operation for the prevention of procreation as should be decided by the said board as most effective. The criminals who would come within the operation of this law should be those that had been convicted of the crime of rape or of such succession of offenses against the criminal law as in the opinion of the board should be deemed to be sufficient evidence of confirmed criminal tendencies. No surgeon performing an operation under the provisions of this Act should be held to account therefor.

Except as authorized by the above Act, every person who should perform, encourage, assist in, or otherwise permit the performance of the operation for the purpose of destroying the power to procreate the human species or any person who should knowingly permit such operation to be performed unless it was a medical necessity, should be guilty of a misdemeanor.

Bills in the Senate.—Dr. HARRIS read an Act to amend the public health law in relation to cadavers.

Dr. Harris read an Act to amend the domestic relations law, in relation to the issuing of marriage licenses. This was introduced by Mr. Duhamel. No license to marry should be issued except after each party to the contract has presented to the clerk a certificate from a doctor of medicine stating that he had examined such applicant for a marriage license and that such applicant was not afflicted with any communicable venereal disease. A person procuring such a license by fraud, false representation, or pretense, a doctor of medicine issuing such a certificate knowing the statements therein to be untrue or without having examined the applicant, a license clerk issuing such a license knowing the certificate to be false or untrue or in violation of the provisions of this article, a person solemnizing a marriage knowing that the provisions of this article had not been complied with, was guilty of a misdemeanor.

It was moved, seconded and carried that these matters be referred to the Delegates of the Medical Society of the State of New York for action.

SCIENTIFIC SECTION.

DR. BROOKS H. WELLS, VICE-PRESIDENT, IN THE CHAIR.

Geriatrics.—Dr. IGNATZ L. NASCHER read this paper. (See page 752.)

Dr. JAMES J. WALSH stated that they knew many things which were not so. The Egyptians rarely partook of meats or alcohol. In the consideration of old age at least three factors should be thought of, overwork, overindulgence in liquor or tobacco, and the conditions which accompanied the so-called strenuous life.

Dr. HEINRICH STERN said that Dr. Walsh had just stated that "we know many things which are not so." When he mentioned less than a minute ago that the old Egyptians hardly ever partook of meats or alcohol he uttered one of those things which were not so. Without wishing to go into details, because these did not at all pertain to the subject under consideration, he could not refrain from recalling the soldier caste in old Egypt. The military hereditary classes in the land of the Nile subsisted almost entirely on meats and alcohol. Their fierceness of character, their brutality, their warrior nature were produced by this food; meats and alcohol were purposely prescribed for them in order to develop the highest possible military qualifications. We knew that the Pharaohs belonged to the warrior caste, and we knew that they and their vast households did not thrive on an exclusive diet of dates and sugar water. He was glad that one man in this country had taken and given a name to the subject of "geriatrics." He had listened very carefully to what Dr. Nascher had to say to-night, and he had carefully perused all he had written on this subject for the past two or three years. The author had not offered any original thoughts upon the subject, but it was sufficient that he had called attention to a long neglected field which belonged to the general practitioner. This neglected branch of medicine would soon receive due consideration from the profession, even if only on account of the happy name which Dr. Nascher had coined for it. The statements to-night did not convey the exact standpoint of Dr. Nascher on the question of senescence and senility. It seemed that he had not made it clear to himself that we had diseases of old age and diseases in the aged. The former were pathological conditions which were consequent upon senile alterations. They comprised the specific affections of old age. The latter were nothing but modifications of the usual diseases which were apt to occur at any period of life. In a book on senility and its diseases, the conditions resulting from the senile changes *per se* should occupy the principal parts thereof. The modifications of ordinary diseases as they occurred in advanced life should occupy second place only. On no account must geriatrics become a specialty; it ever was and must remain part of the domain of the general practitioner or the internist. Healthy old age, of course, was a physiological condition. It was what Cannstadt in 1839 had denominated as "senile involution." Senescence was merely a phase of life in which we were confronted with reduced functional activity of the organism. To consider it a disease, as some had done, was sheer nonsense. It might be compared in a certain sense with normal childhood. In this period physiological activity was as yet not fully developed, the individual had not as yet matured; in senescence physiological activity was on the decline, the individual was beyond the zenith of life. It should be the foremost endeavor of the geriatrist to establish what one might call "the hygiene of old age." He should seek to prevent pathological changes which were the consequences of the period of diminished functional activity; he should try to maintain the metabolic and catabolic equilibrium; he should foster the interactivity, the vicarious function of the various cells, tissues, and organs, and, though all the functions were more or less declining, he should try his utmost to avert any and all decompensations which were prone to be followed by disturbances of the systemic equilibrium. His work should really start with the thirty-fifth year of an individual; it should be entirely based upon the biological conception of senility, *i. e.* the normal and slow decline of the organism. And again, the geriatrist must never lose sight of the one great fact: that all wanted to grow old, but that none of us wanted to be old. All wished to live through a green old age.

Dr. ROBERT ABRAHAMS said that Dr. Nascher deserved to be called "the old man's friend." For a long time he had put forth all his fine literary energies with one single purpose in view, namely, to interest the medical profession in the welfare of those who were bowed down with age. One had but to enter a home of the aged to realize the meaning of the psalmist's prayer. "Cast me not off in the time of my old age; forsake me not when my strength faileth." And yet it was true that from time immemorial the old and decrepit were the care of charity instead of the problem of the physician. In the face of this, Dr. Nascher's plea for the serious study of senile conditions merited more than a respectful hearing. Dr. Nascher complained of the paucity of literature on the subject of diseases of old age. This was not quite so since in his paper he referred to books and monographs on diseases of old age enough to fill a five-foot shelf. He did not see the unmixed intellectual joy in the multiplicity of books on one subject. Perhaps many of them wished that there were as few books on pediatrics as on geriatrics. Dr. Nascher found fault with the American physician who neglected the study of senile changes. Reference to American authoritative works on medicine and surgery, reference to American works on physical diagnosis would measurably contradict this assertion. And if after this they were still charged with the neglect of the old man they could trace the fault to an evil which was deep rooted in unreasonable prejudices against autopsies. One might by strenuous argument, threat, or subterfuge secure the permission of an autopsy on a young person, but never on an old one, for the answer was, "What's the use, the man died of old age." Dr. Abrahams said he had been visiting a home for the aged for more than fourteen years and had never yet performed an autopsy on one of the many hundreds who sailed to the eternal shore. This prejudice was unknown in civilized and enlightened European lands, and that accounted for their being in this respect ahead of this country; the remedy lay with the education of the people. "What constituted old age," or to put it differently, "when was a man old?" There was a great deal of truth in the remark that age did not depend upon years, but upon temperament and health; some men were born old and some never grew old. Psychologically temperament was an index to old age. A man or woman who was rarely at peace with the world, who was forever irritable and grouchy, and who was never without a chip on the shoulder, whether forty or twenty, was a nutritive medium for the microbe of old age. The crusty old maid and the cranky old bachelor were examples of this. Physically they had to fall back for signs of old age on the cardiovascular system and some of the other internal organs. The study of the arterial system compelled them to divide senility into two types, the normal and the abnormal. Normal senility began at eighty, until then it was only a matter of advancing years. The abnormal might begin at twenty. If arterial changes were a criterion of a man's age, then he would say that this abnormal type of senility was very much on the increase both in men and women, young and middle aged. To his mind it was quite clear that the individual who was the victim of a slowly developing degenerative process in the heart, lung, kidney, liver or any other important organ was a prey to premature senility, and in effect it was the same senility seen in the man or woman of eighty, though the sufferer might be less than forty. Young people were more likely to show the effects of lesions of the heart than old people. In this connection he begged to dissent from Dr. Nascher's dictum that aortic insufficiency was the almost universal valvular disease of old age. In an experience covering many hundreds of cases carefully examined aortic insufficiency was the rarest of all the valvular deformities in the aged. The lesions of the valves most common were aortic stenosis and mitral insufficiency. A very important sign of senility either in the young or middle aged was impotency. The occurrence of sexual incompetency was not only an index

of abnormal senility, but its psychological effect tended to grieve, worry, and age the unlucky individual. Conversely the continuance of the sexual function into and beyond the allotted years was a cheerful omen of healthy vigorous old age. They would have to visit a home for the aged to verify the correctness of his observations. There they would behold men of eighty, and some older, strut around like roosters with fine feathers casting amorous glances at the shrunken, shriveled and loveless old women. He had never noticed the reverse even with sufficient allowance for modesty. Such men, though possessing years, died young.

Dr. L. F. Bishop thought the blessing that had accrued to old people was the use of the automobile; its use gave them plenty of fresh air and a wide range of observation, promoted their health, and made them better in many ways. It seemed to him that every one who reached old age so-called was exposed more to autointoxication and the approach to old age depended largely upon the development and progress of this intoxication. With regard to blood pressure there should be established a certain standard and one which in these people should not be interfered with.

Dr. A. Jacobi said that if the use of an automobile meant an early death, he was going to die young. So far, however, as arteriosclerosis was concerned, they were all in the same boat except those who had not reached the age of thirty-five; that was the age at which arteriosclerosis began. In elderly people the temperature should not be taken by the mouth, for the readings could not be relied upon; it should be taken in the vagina or in the rectum, and, if they would compare their findings with the temperature taken by the mouth, they would find very different readings. In the paper read he said it was not mentioned that age began in the cells and not in the tissues of the body; the organs in a normal old man were smaller because the cells were shrunken and, therefore, the tissues became flabby. In an old man the skin could be raised anywhere, but this was not so in an infant. The cells that first disappeared in old men were the sexual cells; it was seldom found that a man of seventy or eighty had a normal semen. With regard to arteriosclerosis the condition of the aorta and the blood-vessels of the lower extremities differed; in the aorta there were marked changes in the intima; in the lower extremities the changes were more marked in the arteries of the muscles. It seemed as if there was an intermittent claudication, as it were, which appeared in fairly early life, among those of about thirty or forty years of age.

Free Post-Graduate Medical Instruction.—Dr. George Mannheimer read this paper. (See page 755.)

Dr. Arpad G. Gerster said that we were all getting post-graduate instruction every day. He had been connected with post-graduate schools for fourteen years and came in contact with medical men who sought instruction—they were seekers after information, but he found that few of them really knew just what they needed. They did not comprehend the importance of a knowledge of the fundamental principles which pertained to the art and practice of surgery; teachers should teach more of these fundamentals, because these man lacked especially in anatomy, physiology, and pathology. To teach these men the fundamentals should be the chief function of post-graduate schools.

Dr. Emily Lewi said that it had become quite the fashion to talk of the passing of the general practitioner; as a matter of fact we had of our own accord ushered in the day of prophylactic medicine by enlightening the layman to such an extent that the family practitioner felt the change of attitude and increased intelligence. These signs of the times, together with the almost universal limiting of families, was one side of the story. On the other hand, when the time should come that a layman who had a cough immediately procured a specialist, one who had a pain in the orbital region, a neurologist, and one who had a dry throat, a laryngologist, when that time came, it would be time enough to relegate the family doctor to the régime of the past. The ranks of the general practitioner had been depleted by those who had affiliated themselves with laboratories, health boards, or had gone into specialties, while the general practitioner, in a city like this, had not the stimulus to resourcefulness and versatility which in the experienced country doctor was such a factor in his usefulness. It seemed a duty to place the patient in the hands of those who worked with greater skill. Therefore in the fields of activity left to them they demanded better educational opportunities in order that they might better serve the public which still made demands upon them. In the last two decades they had practically been overwhelmed by the turn of medical events, each new event dramatically exploited by its devotees. The general practitioners needed post-graduate education in order to keep their balance amid what at times seemed confusion almost to chaos. They thought that they were entitled to a judgment as to the value of group work as done in the hospitals. They desired to know to what extent the real and honest deductions of the average laboratory elucidated and clarified clinical data. They needed this post-graduate education in order to renew their faith in the value of their eyes, ears, and finger tips, and to increase their usefulness notwithstanding the adjuvants of the past decade. Again, the closer affiliation between practitioners and hospitals would give the internes and attendings knowledge of end results, the real end results. They had to listen to reports of appendectomies discharged cured in nine days when the general practitioner had cared for the patient with chronic peritonitis for five months. Subsequently they saw the patients with "cured ulcers" quickly die of carcimona. To follow up afterwards and to throw light on the previous history of patients would be one of the delights of the new régime. It might become possible for the general practitioner to become acquainted with the laboratory work connected with his practice in the nearest hospital laboratory. In fact, this might become a necessity if the general practitioner of the future was to continue laboratory work throughout his career. Again, if more thorough work was to be done and cases were to be interpreted for the profession, discussion to be held, etc., it would be physically impossible for one physician to do justice to more than one hospital appointment, and this would give opportunities to a larger number of physicians. The practitioner would furthermore be able to form a more rational judgment as to the physician who could honestly be of value as a consultant, who had a larger outlook, a comprehensive biological view. If there should be any fountain heads thus brought to light they would all know where to drink. Therefore they asked the cooperation of directors with attending physicians in order that those who had the chosen places might use their influence for the rank and file of the profession who to-day were meted out a mere tolerance and too often an antagonism not deserved. All of the brains, talent, and industry were never concentrated in one class and the experienced practitioner had a distinct value even to the hospital; they asked that this value be recognized and enhanced.

Dr. Mannheimer moved that a committee be appointed for the purpose of ascertaining what institutions would be available for post-graduate instruction along the lines laid down in the paper. This was seconded.

Dr. Arpad G. Gerster offered an amendment that a committee be appointed to consider the question and report back at a later meeting. This amendment, with the consent of Dr. Mannheimer, was seconded and carried.

Camphor and Pneumococci.—Dr. Augustus Seibert read this paper. (See page 750.)

Dr. Robert Coleman Kemp referred to an article which he had published November 30, 1911, in the *Boston Medical and Surgical Journal* on "Colon Bacillus Infections, with a Report of Double Pneumonia and Purulent Bronchitis (Colon Infection) with Recovery." The patient was forty-four years old and was operated on by Dr. Frank Hartley for a right inguinal hernia, and many subsequent infections followed, all due to the colon bacillus. There occurred a double pyelitis, cystitis, double pneumonia, purulent bronchitis, two attacks of colitis, and a myocarditis. Dr. Hartley operated on March 2. On March 11 the patient complained of pains on the right side of the chest, and on the following day a slight dry pleurisy was noted. On March 14 Dr. Kemp found a small pneumonic area at the right base. On March 16 the patient had a sudden attack of heart failure, and he was nearly pulseless, in spite of heroic stimulation and oxygen. Digitalis, caffeine, sodium salicylate, strychnine, and other stimulants were administered every two hours. In addition he had hypodermic injections of camphor, hourly doses of five grains for sixteen hours, in all 80 grains during this time. The patient's chest was kept thoroughly oiled to prevent blistering and boiling hot stupes were used every three minutes over the heart and thorax for seven and one-half hours, with renewals later. Twenty-four hot stupes were applied for twenty hours. Dr. Kemp believed that the continuous extreme heat and the camphor injections were the chief factors in saving the life of this patient in his acute heart failure attack. The patient was given 40 to 50 grains of camphor daily for some days by hypodermic injection. Resolution of the right lung was very slow; there was little expectoration, but abundant colon bacilli were found in the sputum.

Dr. Joseph H. Bainton said that during the last few months he had been in the habit of giving from 50 to 90 grains of camphor in these cases of pneumonia, but it

should be borne in mind that this agent could not cure all cases, for some of them were profoundly toxic and the myocardium was so damaged that they would fail to get well. This, however, was no argument against the treatment by any means. In many of these cases the temperature would fall by crisis and not by lysis. Camphor in small amounts, caffeine, and fresh air acted against any paralysis of the vasomotor centers. The use of camphor in lobar pneumonia was perfectly rational and the question under discussion seemed to be the dosage. These patients usually needed small doses.

Dr. George Mannheimer said that he had treated forty-four cases of lobar pneumonia with camphor and wished to report but one interesting case. A few minutes after 12 c.c. of the solution of camphor was administered the patient went into tonic and clonic convulsions and lost consciousness. Within one hour all this disappeared. She had never had epilepsy or other convulsions. Camphor he believed to be the ideal stimulant and he had used it for years in advanced cases of tuberculosis. There had not been one fatal case reported in the literature resulting from the use of this drug. One could use it with perfect safety.

Dr. Charles I. Proben reported four cases in which he had given camphor, 72 grains a day, and the patients got well within five or six days. Camphor could be used in large doses. Even 40 or 50 grains a day could be used without producing depression or any bad symptoms.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Sixth Annual Meeting, Held at Albany, April 16, 17, and 18, 1912.

(Special Report to the Medical Record.)

HOUSE OF DELEGATES.

First Day.—Monday, April 15.

The President, Dr. Wendell C. Phillips of New York City, in the Chair.

Report of the President.—Dr. Wendell C. Phillips of New York said that he had not prepared the usual address but believed that his time had been spent to better advantage in the reorganization of the society. He said that for some years the conviction had been growing upon him that, while the general management of the State Society was well-nigh ideal and that all of the business departments were conducted on a high level, they had not kept pace with their scientific programs, and thereby had missed unusual opportunities for advancement and for making their annual meetings the clearing house for all departments of medicine, surgery, humanitarian institutions, and public health. On the other hand the attendance at the annual meetings had dwindled and there was a manifest lack of interest in the scientific sessions, so that, with a membership numbering about 7,000, they registered only 412 at the annual meeting of 1911. It seemed therefore that in order to increase the interest and swell the numbers in attendance the character, variety, and scope of the annual program should be revolutionized and greatly enlarged. The council had unanimously extended the full power to reorganize the society into sections, to appoint section officers, and, through them, with the aid of the committee on scientific work, to construct the program for the session. It was the opinion of the president that this method of conducting the scientific session should be adopted because it gave a wider scope for the presentation of papers, because it interested all classes of practitioners of medicine and surgery, because it gave an annual opportunity for creating public sentiment in favor of proper legislation in matters pertaining to the public health, and because it bound together in sections men whose interests were similar. In order to provide for the continuance of the work that had been inaugurated it would be necessary to adopt some by-law that would change the present one covering the work now performed by the committee on scientific work. After reviewing the plans used by the American Medical Association and several of the State societies Dr. Phillips said that for this State it seemed desirable that the officers of the sections should in large part constitute the committee on scientific work, and he recommended that the by-law be so changed that a committee on scientific work be constituted, made up of the officers of the sections, together with one person to be appointed by the president, who should serve as chairman of the committee and also as member of the council. He further recommended that the by-laws be changed so as to empower each section annually to elect a chairman and secretary, and that each outgoing chairman of a section should serve on the executive committee of said section for a period of three years. Dr. Phillips also recommended that, as they were going through a formative period, to the council be delegated the authority to appoint the officers for the five sections now in existence or for any other sections which the council might authorize. After considering several other points in regard to reorganization, Dr. Phillips said that several matters of legislation had come before them during the year. A study of the conditions existing in many of the smaller towns of the State would convince any observer that there was something radically wrong with the method of appointment of health officers and a lack of control of their acts. It would almost seem that their legislators were not awake to the importance of the preservation of public health inasmuch as appropriations for public health and sanitation were extremely meager when compared with those for other State departments; for instance, the State Commissioner of Health received $5,000 per year while the State architect received $7,500, and the Attorney to the Public Service Commission $10,000 per year. It was also evident that the method of appointing health officers in villages and townships was open to criticism inasmuch as such appointments were largely of a political nature and often without regard to efficiency. He recommended that the committee on legislation or a special committee be appointed by the society to investigate these matters and to recommend such legislation as might be deemed wise. He then considered a communication from the Department of Education which he had received in regard to ethics and educational standards of the medical profession. This communication spoke of the question of the division of fees and of different measures of education for those who practised the healing art in different ways. An osteopathic member of the State Board of Medical Examiners had stated that in the present undeveloped situation in the schools of osteopathy it would be impossible for the graduates thereof to comply with the proposed requirements of the Board of Medical Examiners. This protest had led Dr. Draper to say that the State must eventually come to the point of exacting differing measures of education and experience from those who practised the healing art in different ways. Dr. Draper asked for careful investigation and reflection on this subject. Regarding this suggestion Dr. Phillips believed it was the duty of this society to place itself on record as opposed to the plan. In regard to the matters of ethics brought up, they were clearly defined in the Code of Medical Ethics of the American Medical Association, and it was the duty of the county societies to see that they were enforced. In regard to a National Department of Health, the speaker recalled that the House of Delegates of this society had passed resolutions endorsing the plan at its meeting in January, 1910. Two bills were now before the U. S. Senate with this end in view, and the society should pass resolutions endorsing such legislation and the members should endeavor to enlist the interest of their senators and congressmen in the subject. National quarantine control of all ports now under State control should also be strongly endorsed, and the many advantages that would follow such a movement should be plainly set forth. In closing, Dr. Phillips said that during the year several letters had been received asking if provision had been made for the care of aged and infirm physicians who were unable to care for themselves. The New York Physicians' Mutual Aid Association had appointed a committee to formulate a plan to care for such of its members as needed assistance. It seemed desirable that the Medical Society of the State of New York should appoint a committee to consider this matter and to confer with the committees of other organizations that might desire to plan some form of relief for worthy members of the profession who were in need of assistance.

Report of the Secretary.—Dr. Wisner R. Townsend of New York presented this report which showed that the membership of the Society on January 1, 1912, was 6,865. He suggested that the eight councilors elected by the eight district branches be elected to serve two years instead of one as at present. This would greatly add to their efficiency and the council would thus always have four councilors of at least one year's experience.

Report of the Treasurer.—Dr. Alexander Lambert of New York presented this report which had been duly certified by a public accountant of the State, and showed that the Society had on December 30, 1911, a surplus of $11,224. The excess of income over expenses for the year 1911 had been $850.

Report of the Council.—Dr. Wisner R. Townsend

presented this report which showed that the Council had held two meetings during the year, one in Albany on April 19, 1911, and one in New York on May 10, 1911, the minutes of which had been published in the *New York State Journal of Medicine*.

Report of the Committee on Publication.—This committee appointed by the Council and consisting of Drs. S E. Getty of Yonkers, H. A. Fairbairn of Brooklyn, S W S. Toms of Nyack, Alexander Lambert of New York, and Wisner R. Townsend of New York reported that at their first meeting on May 31, 1911, Dr. S. W. S. Toms was appointed chairman for the ensuing year and Dr. Algernon T. Bristow was appointed editor. The cost of publishing the journal was $8,034; after deducting receipts for advertisements and sales the net cost had been $4,553. Eight thousand copies were issued monthly. All advertisements of medical preparations that did not conform with the rules of the American Medical Association as adopted by the Council of Pharmacy and Chemistry were rejected.

Report of the Committee on Public Health.—Dr. JOSHUA M. VAN COTT of Brooklyn presented this report During the year this committee had sent out letters inquiring into the laboratory facilities of the several counties in the State. It was found that there was need of facilities in many counties for the proper examination of sputum, urine, feces, gastric contents, blood for malaria, cultures for diphtheria, Widal and Wassermann reactions, and tumors, but it was decided after due deliberation that in view of the unsettled state of the Legislature it would be unwise at present to take any step towards securing any appropriation by the State for laboratory purposes.

Report of the Committee on Legislation.—Dr. R. P. BUSH of Horseheads reported that this committee, in the absence of any specific instructions from the Society, had endeavored to promote the enactment of such bills as seemed to promise benefit to the people and to oppose the passage of those that would, if enacted into laws, tend to interfere with scientific investigation, sanitation, and prophylaxis. The bills which became laws in which the Society was most interested were: A bill establishing a State institution for the study of malignant and allied diseases at Buffalo; it might receive in its hospital and treat without pay cases of these diseases. This bill carried an appropriation of $65,000. A bill making a change in the physician's legal duties in making reports of deaths. The physician reported the cause of death and delivered the certificate to the undertaker who was responsible for the filling out and filing. A bill putting the supervision of cold storage establishments under the Department of Health. This measure prohibited too long retention of food and provided that when sold it must be properly represented. A bill prohibiting the pollution of the waters of the State and providing penalties and a method of enforcing them. A bill prohibiting the sale or gift of hypodermic syringes or needles. Together with the order of a duly licensed physician or veterinarian, the name of the purchaser, the date of sale and description must be recorded and preserved.

Report of the Committee on Experimental Medicine.—This committee, of which Dr. JOSEPH D BRYANT of New York was chairman, presented a report which called attention to the fact that during the legislative sessions of 1910 and 1911 six bills opposing vivisection were introduced. After reviewing the text of each of these the report stated that each of these bills was opposed by this committee both by a campaign of education and by arguments before legislative committees. The presentation to the public of the truth regarding medical research had been maintained by the committee at the expense of much time and money, supported by generous friends of science and humanity. The chief arguments made before legislative committees were made by Drs. James Ewing of Cornell University, William H Park of the New York University, and Simon Flexner of the Rockefeller Institute. In one instance Dr. W. B. Cannon of Harvard University had attended and added the force of his influence. It was recommended that a vote of thanks be extended to each of these gentlemen for their efficient services by the President of the State Society. Only two of the six bills were reported from the committee both of which were signally defeated; the remaining four expired in committee. It was a sad commentary that out of a membership of 7,000 in the State apparently less than one per cent. of this number evinced any appreciable interest in the outcome which should concern each and every member of the society in the profoundest degree. It was hoped that in the future a more encouraging response from members might be reported. It was pointed out that a reorganization of this committee was urgently needed as well as an appropriation of $150 from the funds of the Society.

Report of the Committee on the Regulation of the Introduction of Medical Expert Testimony.—Dr. DWIGHT H. MURRAY of Syracuse presented this report, in which it was stated that the Hon. A. T. Clearwater, Chairman of the Bar Association Committee, seemed to think it was not advisable to introduce any bill during the present year, owing to the fact that the Legislature did not seem disposed to do anything with constructive legislation. If conditions were changed they would endeavor to push a bill to passage in 1912. A supplementary report was also submitted which set forth Judge Clearwater's views on Medical Expert Testimony and contained the recommendation that the resolutions adopted some time ago by the New York Academy of Medicine in regard to medical expert testimony be adopted by the State society.

Report of Committee on Uniform Membership.—This committee, appointed to consider the legality, expediency, and advisability of making every member of a county and State society, *ipso facto*, a member of the American Medical Association, reported that it had held no meeting because the American Medical Association had failed up to the present time to present any definite plan for consideration.

Report of the Counsel.—JAMES TAYLOR LEWIS reported that the year 1911 had been extraordinary in some respects. More suits had been instituted during this year than during any year since 1900, and more cases had been actually disposed of in court than in any year since organized malpractice defense was established. This year had seen the final defeat of every action brought against a member of the State society and defended by the counsel of the society. There were no appeals from any verdict pending, all having been set aside. September of 1911 had terminated eleven years of organized malpractice defense in New York State, during which time upwards of 300 suits had been brought to the counsel for defense, and something over 100 had been actually defended in court. Verdicts had been rendered against the defendants in four cases, all of which verdicts had been set aside. Twenty-three cases had been disposed of during the past year. The counsel was of the opinion that the willingness of members of the State society and others to make use of what was known as indemnity insurance was a potent factor in breeding malpractice suits. He believed that members of the profession should abandon this practice of taking out insurance; it was harmful not only to the man who held it, but to the profession as well. The public had been further informed during the past year of this organized malpractice defense and this knowledge was bound to be of benefit as would be demonstrated by the record of new cases during the coming years. He had formerly been opposed to publicity of this defense, but he now believed that it should be given more publicity, principally for its moral effect on the public. The legal work of the counsel on behalf of the State society had been widely extended outside of malpractice defense. There had been a continual increase in correspondence and inquiry in the nature of consultation with the counsel by members of the profession on various legal questions, which showed the broadening interest of members in the State society itself and demonstrated the desire on the part of members to familiarize themselves with legal questions and principles involved in the practice of their profession, all of which was most gratifying. State societies of other States were continually inquiring through their officers as to the advantages of organized malpractice defense and new efforts in various States were being formulated in this direction. The work of the State society through its legal department could and should be further broadened and the counsel expressed himself as ready at all times to afford legal assistance in any direction to those requesting it.

The recommendations contained in the reports were referred for consideration to a committee appointed by the president.

No Prizes Awarded.—The Secretary, Dr. WISNER R. TOWNSEND announced that two essays had been submitted to the committee on the award of prizes, but neither of them had been adjudged of sufficient merit to warrant the awarding of a prize.

Time and Place of Annual Meeting.—The last Tuesday in April of 1913 was decided upon as the time of the next annual meeting. In response to an invitation from the Monroe County Medical Society, Rochester was chosen as the place of meeting in 1913.

Resolutions Adopted.—Among the resolutions adopted by the House of Delegates were the following: A resolution from the Medical Society of Dutchess County providing that, as it was extremely difficult if not impossible

for the county societies in rural districts to secure the conviction of illegal practitioners owing to the difficulties in securing evidence, the State Society take up this work. A resolution protesting against the suggestions made by the Educational Department that different requirements be permitted for different schools of medicine and that a copy of this protest be sent to the Board of Regents. A resolution endorsing the action of the American Medical Association and of the various county societies in regard to public health work. A resolution introduced by the Committee on Experimental Medicine urging the necessity of instructing the public on the subject of vivisection at all times and by all honorable means and providing for an enlarged committee for the prosecution of this work. A resolution endorsing the bills now before the Senate for the establishment of a National Health Department and one urging the national quarantine control of all ports now under State control.

Second Day—Tuesday, April 16.

Election of Officers.—The following officers were elected for the ensuing year: *President*, Dr. John F. W. Whitbeck of Rochester; *First Vice-President*, Dr. W. S. Gleason of Newburgh; *Second Vice-President*, Dr. William F. Campbell of Brooklyn; *Third Vice-President*, Dr. R. Paul Higgins of Cortland; *Secretary*, Dr. Wisner R. Townsend of New York; *Treasurer*, Dr. Alexander Lambert of New York; *Chairman of Committee on Scientific Work*, Dr. Thomas J. Harris of New York; *Chairman of Committee on Public Health*, Dr. Joshua M. Van Cott of Brooklyn; *Chairman of Committee on Legislation*, Dr. R. P. Bush of Horseheads; *Chairman of Committee on Arrangements*, Dr. Edward W. Mulligan of Rochester; *Delegates to the American Medical Association*, Dr. Wendell C. Phillips of New York, Dr. William D. Johnson of Batavia, Dr. Dwight Murray of Syracuse, Dr. James P. Warbasse of Brooklyn, Dr. Grant C. Madill of Ogdensburg; *Alternates*, Dr. O. E. Jones of Monroe, Dr. Leo H. Neuman of Albany, Dr. Rosalie Slaughter Morton of New York, Dr. Walter Lester Carr of New York, Dr. Julius Ullman of Buffalo.

Report of Reference Committee.—Dr. Egbert Le Fevre of New York made the report for this committee and submitted the following recommendations and resolutions which were adopted by the House. A recommendation providing for the appointment of a special committee for revising the By-Laws which should report at the next meeting. A resolution providing that the Council be authorized to designate the sections for the following year and to appoint officers for the same. A resolution endorsing the principles of ethics of the American Medical Association on the subject of fee splitting and providing that whereas it was essential to the dignity of the profession and the welfare of the public they urged that county societies use every effort to suppress the giving or receiving of commissions without the knowledge of the patient. Resolutions providing for the appointment of a committee to confer with other organizations on the subject of providing assistance for aged physicians who were in need.

GENERAL SESSIONS.

First Day—Tuesday April 16.

The President, Dr. Wendell C. Phillips in the Chair.

Invocation.—The Reverend Alexander H. Abbott, Pastor of the Emmanuel Baptist Church, made the invocation.

Opening Remarks by the President.—Dr. Wendell C. Phillips said he had only to repeat that he had employed his time in reorganizing the work of the Society and left it to the members to decide if he had not better employed his time in this way than by writing an address.

Address of Welcome.—Governor John A. Dix made a short address of welcome in behalf of the State of New York.

Address of Welcome.—Mayor James B. McEwan of Albany welcomed the Medical Society of the State of New York in behalf of the City of Albany and spoke of the gratitude that humanity owed the profession as a whole and of the gratitude he bore to the profession and especially to one individual physician to whom he owed his life.

Greetings from the American Medical Association.—Dr. Abraham Jacobi made this address in which he stated that ten years ago he had been president of the Society and a member of the committee which had adjusted the relations of the Society with the American Medical Association. Six years ago they had recovered their legitimate relations with that great body. The State Society was now entering on a new era and he thought this a fitting time to urge that, as only one-half of the members of the State Society were members of the American Medical Association, they endeavor to make the membership in the larger organization more general. By such cooperation they would add to the efficiency of the American Medical Association in its work for the public welfare.

Relation of Exact Science to Medicine.—Dr. Harvey W. Wiley made this address. He said that in the shadow of the great disaster that had brought sorrow to a thousand homes in this and other countries it was of some moment that they were gathered here in the interest of saving life and promoting human welfare. They spoke of great battles and great disasters with horror but forgot that many hundreds died yearly of avoidable diseases. He compared the puny endeavors of men to the conquering powers of nature and said that it was a mockery we could not fail to recognize when any work of man was called "titanic." The time might come when by some sensitive device to detect temperature the approach of an iceberg might be foretold and that by the advance of medical science they might prevent premature contact with death. He considered medicine as applied Christianity and believed that the minister and physician should work hand in hand. He referred to the various senses in which medicine might be considered and said he viewed it in the broad light as that science which dealt with the prevention, cure, and alleviation of disease. He said the popular impression was that a physician who did not give some drug did not know his business but the truth was the physician who did not give drugs often did more toward preserving the health of his patient. The person who took nothing was often in a better environment than he who filled his system with drugs. The speaker then contrasted the medicine of thirty years ago with that of today. His impressions of medicine at that time led him to the conclusion that it could scarcely be regarded as a science, that at the very best it could only have been called scientific impiricism. This empiricism was fast being converted into a scientific reality. After all the human organism was the best physician and the fundamental tenet of medicine was the maintenance of animal resistance against all forms of disease. Dr. Wiley then undertook to show how the advance of science had assisted medicine. He first spoke of the science of astronomy and the influence that astral and meteoric conditions wrought in human environment and expressed the opinion that there was a great field here for investigating just how these external physical conditions affected health. In considering the effect that the science of physics had had on medicine he referred to the phenomena of radiant energy, especially to the *x*-ray and electric light, which had been the means of putting many devices useful in the diagnosis of disease into the hand of the physician. He thought that perhaps the curative effects of radiant energy had been somewhat overestimated. In speaking of the ways in which botany had always lent its assistance to medicine he called attention to the experiments that were being made in the introduction of foreign drug-producing plants and said it would be interesting to see the results of a new environment. In general it might be stated that such a change in environment led to a deterioration in the vitality of the medicinal agent. He went on to show the relation of chemistry to botany and said that this science was not only of service in transforming the medicinal qualities of plants into forms used in medicine but it was most useful in diagnosis and therapeutics. The body was an engine and was governed by the principles of thermodynamics and chemical laws were the basis of the early stages of life. He referred to Professor Loeb's experiments on the origin of life and to the changes that were wrought by a change of chemical environment. Life and growth were just as great a mystery as ever though we did know some of the laws that controlled them. The speaker then touched on the relation of chemistry to physiology, showing that the latter owed its very existence as a science to chemistry. He pointed out how physiology had shown the interdependence of the various organs of the body and that these organs were engaged in the manufacture and distribution of various substances and cited as examples the thyroid and adrenals. Going on to bacteriology he pointed out how chemistry had assisted this science by furnishing the stains which had enabled the microscopist to discover so much that had revolutionized medicine. He referred to the work that had been done in discovering the means of combating syphilis and ventured to prophesy that twenty-five years would see the cancer problem solved. Chemistry did more than seek new remedies, however, it threw light on pathological

changes. It had been within a short time only that the physician had realized the importance of the examination of all excreta and the chemical laboratory was now an indispensable adjunct to the physician. He believed that chemistry would solve the problems of metabolism and that the future physician would be a master in the science of diet and nutrition. Atwater, Benedict, and others had shown how the laws of thermodynamics were applicable to metabolism and there was hope that the empiricism of the present theories would be replaced by accurate scientific knowledge. In speaking of what pharmacology had done for medicine Dr. Wiley warned the physician against the tendency to try new drugs and urged him not to yield to the insistant demands to use a new drug as he thus became an experimenter of the body of his patient. After speaking of the possibilities that immunity held out he said that the introduction of scientific principles into medicine had shown a kernel of truth in all schools and sects that practiced the healing art, only each had exaggerated one idea and thus they had become narrowed. Creeds led to prejudice and battle and narrowed the human mind but science had erected a monument from which the true physician could survey all fields and take to himself whatever was found good. These sciences which he had considered were fundamental and only those grounded in them could with safety and efficiency study the healing art and become true benefactors of mankind.

The Prevention of Insanity.—Dr ALBERT WARREN FERRIS of Watkins read this paper. He said that after having given our attention to the conservation of our mineral resources, our forests, our orchards, and our cattle we at last had a little time to spare in which to give a little attention to our children. There were serums for typhoid, meningitis and diphtheria, vaccination against smallpox, a campaign against tuberculosis and now a movement had been inaugurated to combat insanity. There were three factors at work, an authoritative presentation of facts, an appeal to the taxpayer, and an appeal to the good sense of the ordinary men and women in the community. He asked if there was anyone who knew his family and that of his wife for four generations who could state positively that there was no taint of insanity in his family. There was an impression that the hospitals for the insane were recruited from the so-called lower classes, this was a mistake for records of the hospitals showed that 77 per cent. of the inmates were above the class of the day laborer; they had been producers, taxpayers and useful members of society. In 1910 there were over 32,000 insane in the State of New York, while in 1890 there were about 16,000. In twenty years the population had increased 47.6 per cent. while the number of insane had increased 103 per cent. Probably there had been no such increase if everything were taken into consideration but the fact remained that 6,000 new cases were admitted to hospitals each year, a net increase of about 1,000 cases annually. It was evident that the burden of the care of this large number of insane patients was increasing and the most sensible course that suggested itself was to ascertain the avoidable causes of insanity and to limit the production of this class of unfortunates. A campaign for this purpose had been launched and it had been found that the causes chiefly responsible for insanity were alcohol and syphilis. General paresis without syphilis was unknown and those suffering from this disorder constituted 12 per cent. of the new cases annually. Syphilis was responsible for many other forms of insanity. Syphilis treated in the second stage might be cured but many never recovered from it. About 5,000 of the men in the State hospitals owed their condition to "sowing wild oats." Alcohol was responsible for 50 per cent. of the male insanity. Alcohol was a stimulant poison and too much stress could not be laid on the deleterious effects of even small quantities habitually taken. Its effects were demonstrated in mental enfeeblement, defective offspring and sometimes in insanity. If physical conditions were amenable to hygienic treatment why not mental? Dr. Ferris said the subject was being studied from the viewpoint of environment and heredity and that dispensaries had been established for the treatment of the milder forms of mental disease. In studying these cases the hospital physician solicited the help of the family physician and the consulting physician. There were few committing physicians who ever visited the hospitals for the insane or kept themselves acquainted with the condition of their patients. Dr Ferris urged the establishment of psychopathic wards in connection with general hospitals for the temporary detention of insane patients. In closing he said that the responsibility for the prevention of insanity lay at the door of the physicians of this State.

The Present Status of the Movement for the Prevention of Tuberculosis in This State.—HOMER FOLKS of the State Charities Aid Association made this address by invitation. He said that today every eye had been centered on a spot in the Atlantic where a great disaster had occurred which had cost over a thousand lives, and he wished that the same concentration of attention might be secured for the fact that as many went down every year to death because of tuberculosis. Where tuberculosis was concerned it was not even permitted to give the women and children the first chance. It was many miles further from the Lower East Side of New York to the City Hall than it was from the Carpathia to the Titanic. There it was a mechanical difficulty that was to be fought; here it was ignorance and indifference of men. He hoped that the sympathy that was aroused by the great disaster would remain and become a permanent asset of the State in its fight against tuberculosis. In 1902 the Charity Organization Society, of New York City, began its work in this line and later the work was extended to the State but there were sharp distinctions between the two movements. In the city there was one health officer with able assistants, laboratory facilities and great prestige; in the State there were 1,400 health officers of varying degrees of efficiency who had limited financial resources and were afraid of public opinion. In 1907 little stress was laid on hospital treatment for the tuberculosis patient as a preventive agency; at that time there were only seven agencies outside of New York City for this purpose with a total capacity of 444 beds. To-day there were 22 hospitals with a total capacity of 1,200 beds. In addition there were 11 county and 5 municipal hospitals with a capacity of 1,143 beds. Assuming that in the City of New York there were five living cases to one death there was one bed to every twelve cases. Outside of the city there was one bed to every twenty-one cases. In 1907 there were two dispensaries outside of New York City; to-day there were thirty-three. The speaker laid special emphasis on the services of the visiting nurses. They were the most valuable agency that they now had for finding out where the largest number of cases were. They had found that the overwhelming majority of cases of tuberculosis were unknown, unreported and uncared for. In 1907 there were but two visiting nurses outside of New York City; today there are forty-nine. The necessity for financial relief especially where the victim of the disease was the breadwinner of the family was early recognized. In 1907 only two agencies for supplying such relief were in existence while in April, 1912, there were twenty-seven. Progress had been made in respect to the compulsory reporting of cases but this was not as rapid as was desirable. In 1911, 8,700 cases were reported. It was his belief that only about one-fourth of the actual number of cases were reported. The physician should be not only a good physician but a good citizen and a good sanitarian and should look to it that this law in regard to reporting tuberculosis was obeyed. The duty of supervision of cases of tuberculosis in their homes devolved on the attending physician or the health officer and he preferred that the responsibility should rest on the health officer. He said that he had left the consideration of popular education until the last because he considered it the most important, but the effects of popular education were the most difficult to measure. The large exhibit of the State Health Department had visited all the large cities of the State. Exhibits had been given in fifty-nine villages and at fifty-eight county fairs. The public lectures had been attended by 450,000 persons, over 1,000,000 leaflets on the subject of tuberculosis and its prevention had been distributed to the people, and there were in the State 263 local societies with a membership of over 8,800. As to the results of the movement he did not think that the death rate showed any appreciable diminution. It was falling but this had been the case before the movement was started. He concluded that the death rate varied from month to month and year to year because they arrived at prompt and efficient reporting of cases. The apparent increase in the death rate in the early stages of such a movement was due to more accurate diagnosis and more readiness to ascribe this disease as the cause of death. He did not think the campaign had been in operation long enough to show definite results. He thought the movement had been valuable in teaching the public to appreciate the physician and to employ him. The work was becoming so great that it was rapidly outgrowing the bounds of private philanthropy and should become a matter of public concern and of legislation. From the increase in the number of nurses, hospitals and dispensaries they could hold out the hope that the slogan "No tuberculosis in 1915" might be realized but even then their efforts would by no means be at an end.

PERSONAL OBSERVATIONS OF WASSERMANN'S EXPERIMENTS ON MOUSE TUMORS.*

By O. KILIANI, M.D.,

NEW YORK,

PROFESSOR OF CLINICAL SURGERY, COLUMBIA UNIVERSITY, SURGEON TO THE GERMAN HOSPITAL.

THE entire scientific world is aware that Wassermann has been carrying on for a number of years past experiments in treating animals who are suffering from tumors (tumorkranke Tiere). Since about a year, after a number of experiments in other directions had proved failures, these researches have taken the character of chemotherapeutic experiments on tumor animals, especially with eosin-selenium.

A part of the results achieved by Wassermann with his collaborators, Keysser and Michael Wassermann, has been published in the *Deutsche medizinische Wochenschrift*, No. 51, 1911, and in the *Berliner klinische Wochenschrift*, No. 1, 1912, where the experimental part is described by Wassermann-Keysser-Wassermann and the anatomical part by Hansemann.

As it is more than probable that these experiments and the results achieved will have a direct bearing on our future treatment of human cancer, it may be of interest to this society to hear a report of what, during my recent stay in Berlin, I had occasion to observe in the Royal Institute for Infectious Diseases at Berlin, through the great kindness of Geheimrat Professor A. von Wassermann.

As I may rightly assume that the contents of the two publications named are known to the medical community at large, it will suffice to repeat briefly the fundamental idea of the procedure. I will also omit all historical notes, with the names of others who have worked in the same line or prepared the scientific field for such work, as I want to give you a simple report of a practical surgeon of what he has seen of those animal experiments, which promise to be of such far-reaching importance.

Wassermann starts from the idea that malignant tumors grow more energetically and are vitally stronger than the cells of other organs and that, therefore, they need more oxygen and have a more pronounced affinity for it. As a strongly reducing body, Wassermann selected natrium selenicum and telluricum, the metal of which was found to be reduced by living cells, especially by the cells of those places where carcinoma cells were located. The deposit of the metal was inside the body of the cell, near the nucleus. It is enough to mention that Wassermann carried on experiments with these two salts by local injection into the tumors of mice; but this really was not what Wassermann was after, as he wanted to carry media, which have a destructive power on tumor cells, automatically into the tumor from the blood circulation.

If I speak here of tumors or mouse tumors or tumors in mice, it is always understood that we have to deal with mice which had been inoculated (usually three or four months previously) with a tumor, which had been designated by Ehrlich as carcinoma, or mice which had been inoculated from Schillings' stock.

I shall not take up at all the purely anatomical question of these experiments and leave it to the members of the Society to read the anatomical part by Hansemann in the *Berliner klinische Wochenschrift*, No. 1, 1912.

To try automatically to reach a tumor by way of the circulation, selenium and tellurium were injected into the tail-vein of the mice with absolutely no result, apparently because the metals had been absorbed by other cells. It was therefore necessary, Wassermann reasoned, to find a carrier for the selenium to bring it into the parts where wanted, or, as he expressed it, to build "railroad tracks" on which these preparations could travel to the tumor. It was necessary to select chemical compounds which can be carried into the organism very rapidly, and which possess a strong power of diffusion.

Ehrlich and Wassermann had formerly tested the behavior of fluorescines, triphenylmethan dyes, in the living organism. Of these Wassermann selected finally eosin and similar chemical bodies, and it may be appreciated how industriously this question had been followed when I tell you that at the time of my presence in Berlin chemical preparation No. 256 was tried out. The principal chemical difficulty seemed to be to produce exactly the same chemical body again, after it had been found by a number of experiments to be especially effective; not only this, but these chemical compounds proved to be unstable, that is, they would within a very short while decompose enough to have an entirely different action. For this eosin-selenium and similar chemical substances, where one part acts as carrier for the other chemical part to certain cells or organs, Wassermann proposes the name *cytotrochine*, from *kytos*, the cell, and *trochia*, the track.

Before describing to you the method of treating tumor mice with eosin-selenium, as I have seen it carried out by Wassermann and his assistants, I want to say that most, if not all, of the experiments were carried on with doses near the fatal dose, to get the most striking results, a method which, of course, can be applied only in animal experiments.

A good-sized white mouse weighs about 15 grams, ½ ounce; lately Wassermann has had quite some difficulty, owing to the enormous demand for mice on the mouse farms, to secure enough animals of proper age and weight, a matter which was partly

*Read before the Surgical Section of the Academy of Medicine of New York, April 5, 1912.

responsible for many failures, as the animals were not strong enough. Such a mouse had previously (three or four months) been inoculated with mouse tumor, as I remarked before, either from Ehrlich's or Professor Schillings' stock. The tumor, usually situated on the back of the mouse under the skin, frequently not only attached to but growing into the muscles of the back and other organs, would at the time of the injection have achieved the size from a hazelnut to a walnut; sometimes the tumor would represent from one-third to nearly one-half the size of the animal.

Eosin-selenium, if rightly constituted, is a red powder, according to the color of the eosin, of which you here see a specimen. It is easily soluble in cold and especially in warm water. The solution must not only be clear but lucid. One c.c. of a solution of 1/400, that means 2.5 mg., injected into a vein of an average mouse of 15 grams, will be tolerated; if more is given, the mice die either acutely in convulsions or within the next twenty-four hours. The injection is made in the following way:

With an extremely fine hypodermic needle one c.c. is injected into the dorsal tail-vein of the mouse, after the veins have been dilated by a lighted cigar being carried past the tail a number of times. It is rather a severe test for the assistants to smoke all the necessary cigars, if many experiments are carried on in one day. Since some of the "Präeparateusen" (female laboratory assistants) are to carry on this work, an electric cigar lighter has been substituted for this purpose.

Immediately, that is within half a minute, after the injection of this eosin-selenium solution, the tail, the feet, the ears, the nose, the snout, the eyelids, and the entire eye of the mouse become intensely pink. The excretion of the preparation begins very soon after the injection; the principal part seems to be carried off by the feces, while the secretion through the urine stops after about twelve hours, when the urine becomes again untinted. Most of the mice turn pale again after twenty-four hours, but if the animal does not soon enough return to its natural color and stays pinkish, it usually dies, a fact which speaks for the inability of the animal to excrete the preparation properly.

If the mouse overcomes the effect of the injection of 2.5 mg., and if the preparation was a proper one, a most remarkable effect is to be observed. Three injections are made on three consecutive days. After the third injection the tumor is decidedly softened; then, with an intermission of one day, a fourth, fifth, up to an eighth injection is made, a matter somewhat depending on technical difficulties. After the softening of the tumor has begun, it begins to feel cystic, and finally an empty bag can be felt between the examining fingers, while the tumor has disappeared.

If an injected tumor mouse is killed after twenty-four hours, dissection of the animal shows that all other organs present the normal coloring, while the tumor itself is intensely red, a proof that the eosin-selenium, which has disappeared from the rest of the body, has been held back by the tumor.

If a tumor mouse is killed after the third injection, the tumor shows plainly on dissection a softening and decay, until in the later stages one sees at the post mortem only small débris or granular substance, and finally nothing but scar tissue at the former seat of the tumor.

If the tumor mouse stands the necessary amount of injections, the tumor has disappeared and the mouse is cured of its tumor. In exceptional cases, when the injections had not been carried far enough, but where the tumor had apparently disappeared, recurrences have taken place, but in all cases where the treatment could be carried on far enough the mouse was cured.

There is one great danger to the injected tumor mouse; even if the preparation was not too toxic—when it will kill the animals from the first to third day by poisoning—the absorption of the tumor may prove very dangerous to the animal. It is easy to understand that the tremendously rapid absorption of so much pathogenic material must tax the vitality of the animal to the utmost. This is especially the case if the softening and liquefaction of the tumor began very early, as, for instance, after the second injection. But a large number of tumor mice have been cured, and remained free of recurrence for a number of months, through this treatment.

The softening and liquefying effect of the preparation has been proven as typical, as a law, in now nearly 2,000 experiments on tumor mice.

I will now demonstrate to you the specimens which I owe to the kindness of Wassermann, which he gave me for the purpose of this paper.

In No. 1 you see a normal tumor mouse. Unfortunately in killing, the tail, which is very near the tumor, was torn out, so that a slight hemorrhage into the tumor took place. The two parallel incisions over the tumor show plainly the type, size and consistency of the tumor.

The mouse No. 2 (No. 1803) shows the first stage of the treatment. The animal has received two injections; while the rest of the animal shows natural colors the tumor is dyed red, and decayed, and of mushy consistency, showing beginning reabsorption. The size of the tumor was originally that of a large plum-stone.

The third mouse (No. 1817) shows the second stage. What is left of the tumor over the spine is red and decayed. On the upper right-hand corner, corresponding to the chest, are remnants of the tumor, of lardaceous appearance. The original size of the tumor was that of a cherry.

Fourth mouse (No. 1420), cured mouse. The tumor was originally on the rectus muscles of the loin.

I will now describe the autochromes prepared according to the Lumière method. Mouse No. 1806 is in the first stage (demonstration) mouse 1804 approaches the second stage; the dissolution of the tumor has progressed much further, and mouse No. 1817, corresponding to the mouse No. 1817 in the glass jar, shows the last stage of the treatment.*

The question now arises: Of what value is and will be the experimental work of Wassermann to us practical surgeons? I cannot think of entering into the theoretically scientific question: How far mouse tumor is similar to human cancer, or whether the tumor of a mouse is purely a local disease? I can only say that during my short stay I observed personally two metastases of mouse tumor in the lung, a fact which, I understand, has sometimes been questioned; but it seems to me it is not necessary at all to enter the question of relation of mouse tumor to human malignant growth. Wassermann has succeeded in carrying through the medium of eosin a strongly reducing chemical body (selenium) selectively into atypical growths which grow faster

* The specimens unfortunately, do not easily lend themselves to illustration, as the mice specimens are kept in glass jars and the autochromes cannot be reproduced.

and more abundant than the rest of the organs. If that is possible, it seems reasonable to hope that a treatment based on similar lines will be possible in human cancer.

If chemotherapy can solve this question at all, this tremendous step forward, of reaching tumor cells alone selectively, should bring us very much nearer to its solution.

If this treatment shall be tried in human cancer, and I have no reason to assume that it will not, the method must be, of course, vastly different. The work of the surgeon will be rather increased, as all operable tumors will have to be extirpated first, and only after the most exact removal of the diseased parts, the chemotherapeutic treatment could begin to hunt out, select, and destroy those minimal parts of carcinoma which have evaded the eye of the surgeon or may have been deposited somewhere else. It is at once clear that inoperable tumors, for instance certain intraabdominal ones, could never be the subject of such a treatment, as the more or less rapid softening would at once produce a perforation, as the diseased organ in such a condition would not even stand the intracellular pressure, thus ending the life of the patient abruptly.

As to the possible method to be applied for human treatment, one might expect that the injection into the artery (not the vein) supplying the diseased organ would facilitate the reaching of the growth.

It is needless to say that all further animal and clinical experiments will have to be carried on and out by the originator of the experiments, whom we all can only follow with the most sincere interest.

I wish to add that I regret more than anybody else the wrong impressions which have been created by inaccurate and over-enthusiastic reports, which found their way into the daily press, and wish to close my few remarks with the expression of the deepest-felt thanks to Wassermann, through whose incomparable kindness I have been permitted to watch these experiments.

44 West Seventy-seventh Street.

THE IMPORTANCE OF REMEMBERING THAT ALL PULMONARY PHYSICAL SIGNS ARE NOT THOSE OF TUBERCULOSIS.*

By H. A. HARE, M.D.,

PHILADELPHIA.

PROFESSOR OF THERAPEUTICS IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA AND PHYSICIAN TO THE JEFFERSON HOSPITAL.

Although some members of the profession seem at times to think that the physical signs of early tuberculosis of the lungs have been recognized only within recent years, as a matter of fact they were well studied and thoroughly understood long before the bacillus of Koch was discovered. Those who had not the aid of the microscope in determining the presence of the bacillus were forced to train their special senses to a point rarely reached by their successors whose auditory nerves are lessened in their acuity by the use of phonendoscopes and whose tactile sense in estimating fremitus is often untrained by lack of constant use.

The recognition of the fact that pulmonary tuberculosis is curable in the great majority of cases, if its presence is determined early in the malady, has been impressed so strongly upon the minds of medical men, and the disastrous results of oversight are so often met with, that there is a tendency to regard all abnormal physical signs in the lungs as indicative of tuberculosis unless the symptoms are so indicative of other affections that tuberculosis is manifestly ruled out. In other words, the fact that physical signs are present in the lungs is considered fair evidence that tuberculosis is the cause, and so individuals are classed as tuberculous who are not so diseased. I am well aware of the fact that countless instances can be brought forward in which unrecognized lesions have produced disaster, and I am not seeking to make light of the importance of recognizing that the early diagnosis of tuberculosis is essential. My object is to point out that some cases are not tuberculous, although thought to be so, and to emphasize the fact that there are no physical signs to be found in the chest which cannot be produced by lesions which are not tuberculous in origin. This point can, I think, be put in a concrete form by the citation of several cases.

Case I.—A girl of eighteen years had a history of constant cough for six weeks with practically no expectoration. Her evening temperature often rose to 100°, and she had little appetite. Her loss of flesh amounted to about eight pounds. At the right apex, above and below the clavicle, there was some impairment of resonance on percussion, some prolongation of expiration, no râles, but slight tubular breathing. She had a history of a sharp attack of influenza at the beginning of her illness but no adequate examination of her chest had been made. An examination into the amount of food she had taken daily showed that owing to her anorexia she had not received more than half the calories needed to maintain her weight for the six weeks spoken of. Indeed, it represented less than 1200 calories a day on the average. The diagnosis was impairment of normal lung action, because of infiltration or congestion of the apex as the result of the influenzal infection, with partial starvation. She was sent to the mountains, ordered proper amounts of food and exercise, and returned in about three months, having gained fifteen pounds and with no physical signs. She is still in perfect health. It may be claimed that this is an instance of a cured tuberculosis, but I think not.

Case II.—A man of forty-nine contracted a cough from his adolescent son who in turn had been infected by an epidemic of pertussis at a boarding-school. The paroxysms were so severe that he had to stop on the street to support himself by nearby objects when seized, although he never whooped. After some three months he still had a spasmodic cough and had lost twenty pounds. At his left apex there was prolonged expiration, blowing breathing, and high-pitched resonance on percussion. The loss of weight was due to the exhaustion produced by his cough, the physical signs I believe to be due to a localized emphysema of the lung. He has since become perfectly well save for the persistence of the physical signs to a moderate degree.

Case III.—A physician engaged in sanatorium work presented himself with a history of marked loss of weight, slight febrile movement, malaise, some anemia, loss of appetite, and impaired digestion. At the base of his right upper lobe posteriorly he had dullness on percussion and bronchial breathing. His tonsils were enlarged and their follicles filled with foul secretion. There was slight enlargement of the cervical lymph nodes on the right side. His tonsillar trouble was attended to and successfully. He was told that he had a pulmonary lesion

*Read before the College of Physicians of Philadelphia, April 3, 1912.

and had better stop work and betake himself to a better climate. He then volunteered the information that some years before he had had a pleuropneumonia of the right side of great severity. With the clearing up of his tonsillar infection and proper general treatment he speedily recovered perfect health except for the chest signs, and the diagnosis of pulmonary tuberculosis was revised so as to read tonsillar infection and an old lesion resulting from pleuropneumonia.

Case IV.—A man of about twenty-one lost fifteen pounds in three months. He had a rise of evening temperature of two degrees and very profuse mucopurulent expectoration, amounting to several spit cupfuls a day. At one apex there seemed to be slight impairment of resonance, and some râles were heard. On both sides of the vertebræ there were many râles and whistling or tubular breathing at several points. The diagnosis of dangerously advanced tuberculous disease of the lung was made. I took the liberty of revising this to pneumococcic infection of the bronchial mucosa with possibly some bronchiectasis. The use of suitable expectorants, an outdoor life, and good food resulted in no expectoration, little cough, no râles and a gain of fifteen pounds in three weeks with no febrile temperature. No tubercle bacilli were in the sputum but multitudes of pneumococci, although there was no history of pneumonia.

Case V.—A woman of twenty-one, after a severe tonsillar infection followed by infection of the cervical lymph nodes, developed six weeks later moderate continued fever lasting several weeks, marked loss of flesh, constant unproductive cough, loss of appetite and loss of weight. She complained of a sense of discomfort at the third interspace near the sternum which was increased by coughing. At this point there was distinct blowing breathing and dullness on percussion. The cough became slightly productive because it caused tracheal irritation, but the sputum was negative except for a few pus organisms. The right apex showed distinct impairment of expansion. The diagnosis of early tuberculosis was made but suddenly revised when after a severe attack of cough a teaspoonful of pure pus containing no tubercle bacilli was expelled. Recovery speedily followed. The diagnosis was infection and suppuration of a bronchial lymph node rupturing into a bronchus.

Case VI.—A woman of thirty, remarkably athletic and strongly built, lost strength, health, and appetite and had an incessant cough which failed to be benefited by ordinary measures. A cold shower bath following exercise gave a good reaction but caused such violent cough that chloroform or amyl nitrate was used to control it. Examination of the chest showed on the right side of the sternum, for two inches vertically, distinct impairment of resonance from the second to the fourth interspace with tubular breathing. The *x*-ray revealed a chain of enlarged bronchial lymph nodes on both sides. As the illness had followed an attack of influenza, she was treated by rest and iodide of iron, and then sent South for the winter with perfect recovery as a result; but she and her family were in misery for weeks because of the diagnosis of pulmonary tuberculosis.

Case VII.—A young man in his twenty-first year, a student at Yale, where he had been very athletic during the late fall and early winter, suffered from pain in the stomach, loss of flesh, cough, and loss of vigor. He became pallid and suffered from dyspnea on exertion. When examined by me he was found to have at the right apex tubular breathing, great impairment of resonance, and a few râles. The diagnosis made was tuberculosis, the more so as he had an evening temperature of 101.5°. He became rapidly worse and the area of consolidation of the lung rapidly increased. At the request of the family, one of the older fellows of this college saw him and made a diagnosis of "epidemic influenza." Some time later he was seen by the late Professor Da Costa, whose name I mention because any opinion expressed by him was so well worthy of confidence. His diagnosis was scrofulosis, probably because the cervical lymph nodes were swollen. The blood examination was negative. The spleen was not materially enlarged. The disease ran a very rapid course, ending in death from respiratory obstruction. Towards the end the diagnosis was evident and the autopsy confirmed it, namely, Hodgkin's disease, with the lesions chiefly in the bronchial lymph nodes.

Case VIII.—A woman of twenty-eight years caught a severe cold which lasted for several weeks with persistent cough. An examination of her right apex showed impairment of expansion, impairment of resonance, some prolongation of expiration, and a few râles. The diagnosis was probable tubercular infection, but perfect recovery of health in two weeks and the discovery of the history of a pneumonia in 1908, resulted in a diagnosis of an acute cold with physical signs due to an old catarrhal pneumonia.

I can cite many similar instances.

Another word may be said as to the diagnostic significance of dullness and absence of vesicular breathing at the base of the lungs. Nearly always these result in the diagnosis of "consolidation" or "pneumonia." In severe bronchitis, in whooping-cough, and after operations in the upper abdominal segment the real state is often atelectasis.

Finally, a few words as to the bronchial lymph nodes. It is remarkable that although these nodes are universally recognized in books on morbid anatomy as being often diseased, the practitioner almost never regards them as important facts in diagnosis, yet these are often the cause of marked physical signs. Sahli describes Neisser's method of their diagnosis by the distended finger cot on a bougie and the *x*-ray will often show them. Delafield and Prudden say: "The tracheal and bronchial lymph nodes may be the seat of a variety of lesions which, owing to their situation, as well as for other reasons, are of considerable practical importance. They may be enlarged from hyperplasia in acute infectious diseases; by the development in them of tumors; in leucemia and with especial frequency in tuberculosis. They may become pigmented from inhaled coal or other dust and may atrophy or become fibrous or calcified. In cheesy degeneration following tuberculosis, or in the suppurative inflammation, perforation may take place into the air passages, the esophagus, the pulmonary blood-vessels, or aorta, or into the pericardial or pleural cavities; in this way hemorrhage or secondary inflammatory processes or gangrene may occur. Death may occur from pressure upon the trachea by tumors of the adjacent lymph nodes. Sudden death from asphyxia may result from perforation into the trachea. Pressure upon the pulmonary veins may lead to pulmonary edema. The bronchial lymph nodes are very important as distributing centers of infectious microorganisms, and particularly

as points of lodgment of tubercle bacilli, which have been gathered from the pulmonary air spaces from the pharynx or elsewhere." They also give the following references to other literature.*

Again in Osler's "Modern Medicine" Warthin says: "An acute simple inflammatory enlargement of the bronchial glands occurs in severe forms of bronchitis, pneumonia, and other acute inflammations of the lungs. It is very common in children in association with the acute infectious diseases, particularly when these are complicated with respiratory affections. It is highly probable that in the majority of cases of simple cervical adenitis there is at the same time more or less enlargement of the bronchial nodes. In the ordinary cases the symptoms due to the pressure of the enlarged glands cannot be separated from those of the primary condition; but when the enlargement is marked severe pressure symptoms may be produced. Dysphagia, dyspnea, respiratory stridor, cyanosis, and the physical signs of bronchial stenosis constitute the clinical picture. Should suppuration occur, the abscess may rupture into the bronchi and sudden death ensue. Chronic inflammation of the bronchial nodes is present in chronic bronchitis, bronchiectasis, chronic pneumonia, etc."

Finally, in Spitzka's edition of "Gray's Anatomy" we find these words: "In all town dwellers there are continually being swept into these nodes from the bronchi and alveoli large quantities of the dust and black carbonaceous pigment that are so freely inhaled in cities. At first the nodes are moderately enlarged, firm, ink black, and gritty on section; later they enlarge still further, often becoming fibrous from the irritation set up by the minute foreign bodies with which they are crammed, and may break down into a soft slimy mass or may calcify. Not infrequently an enlarged tuberculous node perforates into a bronchus, discharging its contents into the tube. When this happens there is great danger of acute or pulmonary tuberculosis, the infecting node-substance being rapidly spread throughout the bronchial system by the coughing its presence in the air-passages excites."

French has recently pointed out that the lymph nodes immediately below the right bronchus are often infected, and Siennikow has written a valuable paper in which he shows that these right nodes are very large ones. By their pressure on the bronchus they cause blowing breathing, and by their irritation of the vagus or phrenic they cause cough. There can be no doubt that one of the chief causes of disease of these nodes is tuberculosis, and a valuable paper on this subject is published by Jordan in the *Practitioner* for February, 1912.

My point is not to deny that these nodes are often tuberculous, but that they may be infected by other organisms than the tubercle bacillus, and second, that many physical signs thought to have their origin in the lung tissues are due to partial bronchial occlusion by pressure.

If any one thinks after hearing this paper that I minimize the frequency of tuberculosis, that I fail to appreciate the disastrous results of its presence if not recognized, or that I do not know of the misery that comes to the relatives when a long-drawn-out and hopeless fight ends in defeat, he fails to grasp my meaning.

My object is not only to be always on guard against the ever-present possibility of pulmonary lesions, but also to emphasize the fact that every subacute or chronic pulmonary lesion presenting impaired resonance, prolonged expiration and, for a short time, febrile movement is not tuberculosis.

A most valued assistant said to me when I spoke of this paper, "You may be right, but you will do a great deal of harm by making men careless as to the possibility of tuberculosis in a given case." I think not, because if any state of the lung, save a healed lesion, presents these physical signs the patient should be warned, and should be treated by fresh air, good food, and all other measures to increase vital resistance, which measures are identical with those for tuberculosis. In many instances untold mental misery for the patient and his family is engendered by the sentence of tuberculous infection, and his whole manner and place of living is altered. His career is not only changed in its course but probably narrowed or arrested. He is afraid to plunge into the struggle for success because he is in dread of a relapse or return of his "old trouble." His seniors are afraid to put him in line for advancement lest their act prove a mistaken kindness and cause his breakdown, his chance of getting life insurance is stopped, and even his marriage may be prevented by the blot on the history of his lungs. These are not imaginary theories. I can point out man after man in and out of the profession who have been so hampered. When tuberculosis has been present nothing but thanks for his recovery can be thought of, but where it has not been present a mistaken diagnosis has been a calamity.

The parallel between the diagnosis of syphilis and tuberculosis is exact. Syphilis is very prevalent, it is the most likely explanation of many symptoms and signs, its correct diagnosis is essential for the sake of the patient, his career, and his relatives, but before his morale is shaken by being told that he has syphilis, before his life is changed and he is perhaps intimidated so that he is tied forever to a fear that an old malady is constantly with him, ready to develop at any moment, all the other possibilities of his case should be excluded.

We must be careful that the predominance of tuberculosis does not cause us to commit the patient to the constant woe of worry and alarm, until we have excluded the conditions which produce physical signs in the chest similar to those of tuberculosis.

Treatment of Erysipelas.—T. Pontano believes that there is no internal or local remedy that is of any great value in the treatment of erysipelas, or that has any influence on mortality. Antistreptococcus serum has proven valueless. Cold applications of physiological salt solution, repeated every four hours, although they do not modify the course of the disease or lessen the mortality, protect the part, lessen contagion, and quiet the pain. The author's conclusions are based on the treatment of 1084 cases, with 995 recoveries.—*Il Policlinico.*

ATHLETIC SUPERIORITY OF OUR NEW STOCKS.

By LT.-COL. CHAS. E. WOODRUFF,

MEDICAL CORPS, U. S. ARMY.

EVERY little while some timid soul confesses to a fear that Americans are becoming degenerate and are bound to die out. The British also are occasionally apprehensive over their alleged physical decay and fill the newspapers with doleful wails as to the future of the human race in general, and the English part of it in particular. There is no ground for such absurd pessimism, though as a matter of fact, there is a plenty of evidence that certain types in each nation do have a higher death rate than others, and that there is a constant slow change in the general average. Both civilizations have been built up by immigrants, and it is a law of nature that change of racial residence is always followed by extinction or alteration of type through the survival of the fittest for the new environment. Moreover there has been a constant immigration into the British Islands from the beginning of things human, and the influx of new blood has always kept civilization humming even if each invasion in olden times did destroy part of what it found. The same phenomenon is being repeated in America with the sole difference that the invaders, except in Mexico and Peru, have not destroyed, but are constantly building up. The process of decay of certain types is also quicker in America and the new blood comes into prominence sooner than in England. Very few of the descendants of the signers of our Declaration of Independence are in public life and most of them are nonentities, while immigrants and the sons of immigrants are in the seats of the mighty. The descendants of the signers of Magna Charta controlled England for many centuries though none of that stock is in evidence now; while the present controlling elements date back some centuries and very few are recent arrivals from the Continent.

It is high time that we find out who are the fittest in each part of America. Every bit of evidence is of some value and that is the reason why the tremendous victories of the American Olympic athletes have such a scientific and popular interest. In the *North American Review* of 1907 there is an analysis of the victories at Athens in 1906, and it is shown that to a large extent the American winners were foreigners or of foreign-born parents, while the old pre-revolutionary stocks were in a conspicuous minority. Moreover, it was discovered that the successes were almost exclusively in short events requiring an enormous expenditure of energy in a short time, while in slow contests of endurance the Americans were hopelessly outclassed by Europeans. The phenomenon was interpreted as another of the many proofs that this sunny southern land is highly stimulating but, as in the case of all other stimulants, exhaustion follows in time though perhaps it may require several generations to be noticeable. Northern races always have died out when they migrated this far south, for it must be remembered that most of Europe is north of the fortieth degree of latitude, and the races which first stocked this country always lived north of the fiftieth parallel. The successes of the 1908 Olympic athletes present new evidence in support of those general conclusions and it will be highly profitable to look into it a bit, so that we may not overdo the matter of athletics in the physical training of boys.

About 100 of the best athletes in America went to London for the latter competition. The proportion of foreign born, native born of foreign parents, and native born of native parents was about the same as for men of the third decade of life in the general population as shown by the census of 1900, but when we analyze them more closely some astounding facts are discovered. Eighty-three reported their ancestry, and the results are condensed into the following table:

1. Foreign born	8
2. Both parents foreign born	9
3. One parent foreign born	12
4. One or more grandparents foreign born	22
5. One or more great-grandparents foreign born	2
6. One or more great-great-grandparents foreign born	4
7. Old stock	5
8. Colonial stock of 17th century	9
9. Other native born variously stated	12
	83

That is, about three-fourths of the best athletes of the country are of the stocks which arrived here after the beginning of the nineteenth century, and the great majority of them arrived in the two or three decades following 1840. On account of the "foreign" names among those who did not answer the inquiries these proportions are probably too small.

When we analyze the victors among them, these facts are still further accentuated. Of those who won first, second, or third place, 10 per cent. were foreign born, while 14 per cent. of the non-athletic population of equal age are foreign born. About 43 per cent. were native born of foreign parents as compared with 17 per cent. in the general population, and only 47 were native born of native parents as compared with 68 per cent. as shown in the census. Of the twenty-seven winners whose ancestry is known, three were foreign born, six had foreign born parents, six had one foreign parent, six had one or more foreign grandparents, and one had foreign born great-grandparents. Only one was of old stock, one of colonial stock, and three were native born of native ancestry variously stated. Considering the names it is safe to say that 85 per cent. or more of the winners are of stock which immigrated since 1840. It is not true that the Olympic games were victories for old American families, as so commonly believed.

Now does this mean athletic decay of the old stocks or a temporary greater superiority of the new? Perhaps both conditions exist. The stimulation of southern climes is one of the best attested facts in medicine and anthropology, and the subsequent decay of migrants too far south is also settled. The native children of foreign parents grow bigger than their ancestors, are taller, have larger chests, larger bones and muscles—though much of this is due to better feeding—but they are also quicker, brighter, and more energetic, which is the result of stimulation. So we find great ability for physical spurts in the first, second, and third native generations, after which there is either reversion to the former normal slowness or actual decay. This stimulation of newcomers differs only in degree from the identical nervous tension of northerners recently arrived in the tropics—a stimulation which

completely deceives them as to the dangers of the climate and tempts them to overexertions which are followed by exhaustion or even collapse. The new stocks in America likewise feel better and are more energetic than their cousins who have remained at home under the protection of the mists and fogs of northern Europe. The athletic craze in America could not exist without this stimulation and we find all kinds of clubs and associations patronized by our newcomers, and there is not the slightest doubt, that as in the tropics, they are overdoing the matter.

The birthplaces of the native athletes present more interesting facts. Practically all of them were born north of Mason and Dixon's line, for the six who were of southern birth were so near that line that they could scarcely be considered exceptions—three in Missouri and one each in northern Kentucky, northern Virginia, and Arkansas, and three of the six were winners. The part of the country furnishing no athletes at all has the highest percentage of native born citizens. It has been said that this is due to the fact that no attention is paid to developing athletics in the south, but the absence of athletes is the reason why there is so little time given to these sports. That is, the further south the quicker the physical decay.

The only three foreign born winners were from Ireland, and it is surprising to note that nearly all the contestants were of Irish, Scotch, English, and German ancestry. Latin Europe was represented by one lone Cuban. The contestants average 5 feet 10 inches in height and 158 pounds in weight, even including the little runners like Hayes. These figures are way above the average of the American population as we would expect in such picked men, but there is another reason, they are descendants of the biggest men in Europe—the Northmen—whom they even surpass in height and weight.

American athletes have long held the records for short, sharp contests, and when these Olympic games were over, it was loudly proclaimed that we had now invaded other fields and were victorious in events requiring endurance: but the Marathon race was the only one, and subsequent events have shown the superiority of Europeans. Even a Marathon cannot be said to be a test of real endurance, for it lasts less than three hours, while the normal man is built for low pressure strains for days. The points which placed our team at the head were short races, jumps, vaulting, throwing weights, and light weight wrestling. It is still true that our excellence consists almost wholly in a curious form of nervousness which permits of the expenditure of all our force at high pressure for a short period, so vastly different from the normal nervous slowness which compels a low pressure expenditure over long periods. Instead of being a matter for congratulation, we can well pause and ask ourselves if it is not a sign of overstimulation which bodes ill for the individual victors. Professional athletes are notoriously short-lived, whereas they should live longer than the rest of us.

College amateurs tell a different story, according to Dr. Anderson of Yale University. The death rate of the athletic alumni ("Y" men) in the last fifty years, as far as known, was 7.2 per cent., but 12.9 per cent. of the non-athletes died in the same time. As the latter class contained all the short-lived weaklings who could not indulge in strenuous sports, and the former were picked men of perfect physique with longer expectation of living, it is questionable whether these figures do not show some damage to the athletes. The athletic naval cadets break down in after life sooner than the non-athletes, and all cadets are picked men on an equal footing as to longevity. Whether this break down is due to the congenital or acquired neurotic condition which made it possible to expend much energy in a few seconds as in our short contests—an almost constant symptom of even high grades of neurasthenia—or whether it results from the strains and exhaustions of training remains to be determined. The tuberculosis which carries off an undue percentage of both professionals and amateurs, may be due to the original exhaustion or that of training.

The contestants show a remarkable tendency to blondness—the types which originated under the clouds and mists of northern Europe and which are now known to suffer more than brunettes from the nervous instability due to excessive light. They are the only ones we would expect to excel in sudden spurts of energy. Of eighty-two who have mentioned complexions, forty-three have blue eyes, thirteen gray, six light brown, seventeen brown, and only three dark brown. Hair color is always darker than that of the eyes and does not give such clear evidence of blondness, but even here there were twenty-eight with decidedly blond hair, twenty-six with brown, nineteen dark brown, and only nine black. Among the winners brunetteness is still more rare, for twenty-three had shades of blue and gray eyes, three brown, and only one dark brown, omitting one of part African blood. Twelve had very light hair, thirteen shades of brown, and only two reported hair as dark brown, and none black.

Of the millions of negroes in the United States only two found their way into the team, and one of those, if not both, was part white, and one was a winner in a relay race. Negroes can work long periods at low pressure but are unable to exert their nervous strength all at once like white men, and among whites the brunettes are not so able as the blonds. Similarly only one Indian competed and he achieved nothing except ninth place in the Marathon. The proportion of blonds among the old stock athletes, though less than in the new as we would expect from the diminishing blondness of American families, is apparently considerably larger than in the non-athletic old stock population. That is, pigmentation is protective enough to prevent the stimulation which leads to exertion of this kind. Consequently the brunets, who constitute the majority of our population, furnish a minority of the athletes.

Almost all the points and events not won by the American team were secured by the nations of the northwest corner of Europe, the rest of the world taking so little that it can be considered a victory of the big brawny northmen who have been the world's rulers from time immemorial, and who are largely blond. Of the native born American winners, eight have German ancestry, five English, five Irish, five Scotch, one Welsh, and one Swiss, and the five old stock Americans are probably all English. The races then which are athletic in their ancestral homes are also athletic in America. Methods of training had very little to do with the matter, if anything at all. There is even a still greater significance to these victories of our big blonds, for it is now almost accepted as a fact that this type constituted the primitive Aryans who arose near the Baltic, if not in Scandinavia itself, and who, for 3,000 years, have been migrating all over the world.

carrying and building up civilization by reason of native ability and the stimulation of sunny climates, and then dying out from overstimulation. They were like glaciers melting under the sun, but leaving their speech and civilization in a terminal moraine, as evidence that Aryans were once there.

The athletic superiority of the ancient Greeks is curiously like that of our own, for they too were Aryan northeners who had migrated to a stimulating climate, Greece being at about the latitude of forty. They died out because of their climatic unfitness, and the same thing happens in America, but the constant influx of immigration restores the type here, and America seems destined to be the athletic leader for all time—at least in events requiring a spurt of nervous energy; but the slower, more stolid nervous system of northern Europe will always be the winner in low pressure sports requiring endurance over extended periods. The youthful games on the two sides of the Atlantic will always differ like baseball and cricket because of this difference in nervous tension. Low pressure games like golf are the only ones suitable for both nations and survive because men can play them long after they have lost ability for those requiring youthful high tension. It is to be noted, too, that the middle aged European can indulge in the athletics of youth longer than we can, because they age slower and also because of the lower pressure needed as in cricket. So let us try to introduce low pressure games in which we can indulge until our hair is white, and do away with the system which exiles us to the bleachers thirty years too soon.

CHEMICAL CONSTITUTION AND PHYSIOLOGICAL ACTION.

BY WALTER A. JACOBS, PH.D.,

NEW YORK.

(From the Laboratories of the Rockefeller Institute for Medical Research, New York.)

With the discovery in 1859 by Stahlschmidt[1] that by the addition of a methyl group to strychnine a substance was produced which no longer showed the tetanizing effect of this alkaloid, but possessed a curarizing action, a new era was opened in pharmacological studies. Many pharmacologists and organic chemists became firmly convinced that a certain relationship must exist between chemical constitution and physiological action, and that the mechanism of the action of drugs upon the organism was of a chemical nature. Some turned their attention at first to the chemical study of substances which possessed marked physiological action, with the idea of determining what in the chemical structure of the compound was responsible for the observed effect. But with the meagre knowledge at hand of the constitution of such complex substances as the alkaloids these efforts were soon complemented by the attempts based upon speculation regarding the structure of the alkaloids or the groups responsible for their action to synthetize substances of a similar nature, with the view of producing the same or similar effects. The great progress made in synthetic organic chemistry up to and during this period was reflected in the increasing interest and work done by those engaged in the synthesis of new medicaments. It was thought that by the conversion of substances of recognized therapeutic value by simple chemical transformations into a series of derivatives, that a substance could be selected which would be cheapest and have the greatest curative value with least injury to the organism. Through such efforts as these an enormous number of new preparations were made, but compared with the great labor expended and in spite of the recommendation of their exploiters but few proved of value.

Of these the greatest achievements were obtained in the group of antipyretics and anesthetics. In the antipyretics interest centered upon two classes of substances of the type of antipyrin and phenacetin. The discovery of antipyrin was the culmination of efforts based upon a false idea regarding the structure of quinine and directed toward the preparation of substances which would possess the properties of this alkaloid. Phenacetin and the numerous preparations related to it owe their discovery to the observation that anilin[2] and acetanilid possessed antipyretic and antineuralgic properties. But the bad effect of these anilin derivatives upon the blood and the observation that such substances are oxidized in the organism and excreted as para-amido phenol[3] led to the preparation among other para-amido phenol derivatives of para-acetamido phenol-ethylether or phenacetin. Other important results were achieved in the discovery by Baumann of the anesthetizing properties of sulfonal and trional, and by Fischer and Mering of veronal. Close upon the acquisition of knowledge regarding the structure of cocaine and of the groupings responsible for its action there followed the synthesis of such local anesthetics as eucaine by Merling and orthoform and nervanin by Einhorn. Although but few out of the hundreds of preparations which have been made have offered any promise from a therapeutic standpoint, nevertheless there has resulted a large amount of experimental material of real theoretical value in so far as it has afforded a picture of the significance of certain groups, and arrangements of groups in the molecule in determining the effect upon the organism. As an instance may be cited the following:

Following the experiment of Stahlschmidt, and with the idea that the methylation of strychnine occurred on the tertiary nitrogen atom forming a substituted ammonium base, Brown and Fraser[4] methylated a number of other alkaloids and obtained the striking result that independently of the action of the original alkaloid the new substances always exhibited a curarizing action. These results were followed by others and culminated in the observation of Böhm[5] that by the same methylation curine, a but slightly toxic alkaloid occurring with curarine in curare could be converted into a base showing all the properties of curarine which is over two hundred times as toxic. More recent experiments[6] have demonstrated that the nitrogen as such is not necessary to induce such effects for the substituted phosphonium, stibonium, arsonium, iodonium, and sulfinium bases which are analogues of the ammonium bases having phosphorus, antimony, arsenic, iodine, and sulphur in the place of nitrogen possessed like curarizing properties.

Such significant results as these were also obtained in numerous studies in the alkaloid series, but the subject is of too complicated a nature to treat here.

This synthetic tendency and the study of groups have had their foundation in the chemical conception of the action of substances in the organism, and though here and there a few laws were formulated to explain the action of certain types of sub-

stances but few attempts have been made to construct general theories regarding the relationship between constitution and action. Schmiedeberg[7] was the first to furnish explanations for the action of substances mainly of the aliphatic series. The activity of aliphatic substances depends above all upon physical and biological factors. The resorbability plays a big rôle. Further, the solubility in water and volatility at ordinary temperature are of distinct importance. The volatile hydrocarbons of petroleum, for instance, show the characteristic narcotic action of the hydrocarbon group, whereas the liquid nonvolatile members which are also insoluble in water are entirely without action. The activity as regards the alcohol group, *i.e.*, the narcotic action, is conditioned by the number of oxygen atoms in the molecule. All substances of this group containing two or more oxygen atoms show little or no action. If a compound, as for instance paraldehyde, is composed of several independent hydrocarbon groups, it is active when at least one has no, or not more than one, oxygen atom. For substituted substances Schmiedeberg formulated the following laws:

By the substitution of aliphatic radicals in very toxic atomic groupings the action is modified in intensity as well as in character. As examples may be cited the comparatively nontoxic nitriles and isonitriles, of which the former is a direct substitution product of prussic acid. On the other hand, the introduction of certain groups into the hydrocarbons may deprive them of their narcotic action. This is well shown by the mono-, di-, trimethylamines. These all possess an action characteristic of the ammonia end of the molecule. They produce no narcosis. When the compound, as in the ethers and esters, are composed of two groups joined by oxygen, the action depends upon the nature and properties of the two components.

More recently a somewhat fantastic attempt was made by Oscar Loew[8] to explain in a purely chemical way the action of all toxic substances. He starts with the assumption that living protoplasm has in its molecule labile aldehyde and amino groups. He regards as poisons all substances which in very great dilution react with these groups, and their toxicity as proportional to this reactivity. The last word, however, in the attempts to explain the connection between constitution and action was spoken by Ehrlich.

Ehrlich[9] realized from the start the great importance of distribution in the organism. Here and there a few observations had been made regarding the distribution of substances, but from the Ehrlich standpoint too little significance had been attached to this factor in determining action, and to this he attributes in part the many failures which up to this time had characterized the efforts to synthetize medicaments. The fundamental conception of Ehrlich's theory of action is that the distribution, *i.e.* the selective affinity of substances for particular organs and systems is a function of their chemical constitution. To support this view he brought to his aid experiments on synthetic dyestuffs, and to explain his results he borrowed the conceptions of Witt and Nietzki regarding the relationships between color and constitution. According to Witt a few groups, such as the azo and nitro groups, are responsible for the dye nature of substances of which they are a part. These so-called chromophore groups lend, however, only a chromogen nature to the substance. In order for the real color to appear certain acid or basic auxiliary groups, namely, the phenolic and amido groups are essential in the molecule, and the nature and intensity of the color depend upon the number of such auxochrome groups and upon the extent to which the free hydrogen of these is substituted by ethyl, methyl, and the like. So, also in physiologically active substances, certain groups are of a toxophore nature, such as the anesthesiophore benzol group in cocaine, while to the basic complex of the alkaloid containing the tertiary nitrogen atom an auxotoxic character must be ascribed.

Having recourse to anatomical and histological examinations, Ehrlich made a large number of dyes the subject for study. In particular he observed that the power to stain the grey nerve tissue was possessed by only a few dyes, particularly of basic nature. Alizarin is the only acid dye with the auxochromic phenol groups which presented an exception. By the introduction of negative sulfo groups into these dyes they were completely deprived of their neurotropic property. This evidences a change in the selective distribution in the organism as determined by constitution. The experimental material affords numerous other examples. To explain, however, how a substance of a certain chemical character is selected by this or that cell, recourse was had to purely physical explanations. A fiber of wool immersed in a picric acid solution of the highest dilution will be stained by the dye. In the same way the tissues may remove some of the poison introduced into the circulation. As regards dyeing two theories exist—that of salt formation and the Witt-van't Hoff theory of solid solutions.

In the solution idea Ehrlich sought the explanation for the phenomenon of localization. This localization may be regarded as a shaking out process. That here no chemical union could exist was shown by injecting animals with a great variety of substances such as thallin, anilin, the alkaloids, phenols, etc., and after awaiting the usual time for completed distribution it was found possible to extract by suitable solvents the substance from any of the tissues infused. The decolorization of brain tissue stained with methylene blue and of the fuchsin kidney was shown in typical manner by ether or alcoholic extraction. In some instances there is a possibility that a very reactive substance might form a stable chemical union with the constituents of the protoplasm, but these are few, and to explain localization in general we must turn solely to physical phenomena. On the other hand, for the furnishing of the necessary relationships between the molecule of those substances available as foods, a chemical union with the protoplasm must be assumed. Experience with the bacterial toxins has shown a like requirement, and perhaps in the fact that the toxins possess a haptophore group and other toxic substances do not the reason may be found why workers up to now have been unable to produce any sort of immunity toward simple substances of known composition.

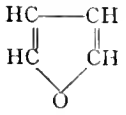
The theory of narcosis of Overton[10] and Meyer[11] is likewise based upon a purely physical conception. Here all chemically indifferent substances which are soluble in fats and fat-like substances must produce narcosis in all living protoplasm in so far as they can be distributed therein. This action will be most marked upon those cells in which lipoids predominate and the relative strength of the narcotic is dependent upon the

partition coefficient between the other cell substances (mostly water) and the fat-like constituents. This explanation restricted to chemically indifferent narcotics has served its purpose well, but when the attempt is made to apply it to chemically active narcotics, such as morphine, considerable stretching is necessary. For example, morphine possesses a phenolic hydroxyl group. To this is attributed the narcotic action of the alkaloid for when by chemical means this group is changed to a methyl ether group codeine results which no longer produces narcosis.

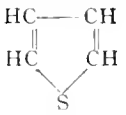
Of all of these theories the best that can be said is that they are but the crudest pictures of the conditions and influences which really determine physiological action. A theory which attempts to explain all phenomena of selection and action from only one standpoint, whether chemical or physical, is bound to meet serious obstacles in the enormous complexity of the relationships that must exist between the tissues and the unendless variety of active substances. In all pharmacodynamic studies the fate of the substances in the organism must be thoroughly studied, for it is essential to know whether the observed action is due to the substance itself or to a transformation product of the same. For instance, it has been proven by Hinsberg[12] that all substances of the phenacetin series which possess antipyretic properties are changed in the organism to para-amido phenol, and that the degree of this action is proportional to the amount of this substance found in the urine. Those derivates of anilin which are not changed to para-amido phenol are not febrifuges. The conclusion then is that the amido phenol is responsible for the observed effects. On the side of the acting substance we possess considerable empirical data obtained with both active and inactive substances, which afford us a picture of how certain groups in certain positions in the molecule act, or how certain groups when placed in the molecule either strengthen or weaken the action characteristic of the mother substance. I shall describe briefly the significance which is attached to the presence in the molecule of certain groups and configurations.

The saturated hydrocarbons[13] of the aliphatic series produce by inhalation anesthesia and sleep, in large doses resulting in death through asphyxia. With the higher members of the series the action is more pronounced. The degree of their toxicity and the duration of anesthesia increases with the number of carbon atoms. The lower members produce narcosis by the exclusion of oxygen, whereas the action of pentane and hexane is more deep seated. According to Lauder Brunton and Cash the principal action of the lower members of the series consists in their stimulating and anesthetic action upon the nerve centers. In the aromatic series the hydrocarbons affect the motor centers more than the sensory, so that instead of anesthesia, tremor, convulsions, and paralysis result. The simple halogen substitution products like chlorbenzol, brombenzol, etc., exhibit a similar action. Naphthalin slows the respiration and acts as a febrifuge by decreasing the metabolism. In general the aromatic nucleus has marked antiseptic properties. A one per cent. solution of phenyl urea, for instance, is as strongly antiseptic as sublimate. Whereas the aliphatic diamine cadaverin is little toxic, the aromatic toluylendiamine shows the toxic influence of the aromatic nucleus by producing jaundice and hematuria.

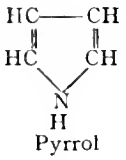
The chemical analogy with benzol shown by furane, thiophene, and pyrrol is further evidenced by a similar pharmacological action.



Furane

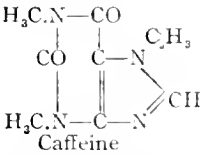


Thiophene

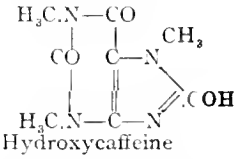


Pyrrol

The entrance of the hydroxyl group into substances of the fatty series tends to diminish their action, and the more these groups enter the molecule the weaker is the action. From the narcotic aldehyde, CH_3, CHO, by condensation the inactive aldol, $CH_3.CH(OH).CH_2.CHO$, is obtained. By hydroxylation of ordinary alcohol the inactive glycol, $CH_2(OH).CH_2(OH)$, is produced. From the strongly narcotic hexyl alcohol, $CH_3.(CH_2)_4.CH_2OH$, by complete hydroxylation mannite, $CH_2OH.(CHOH)_4.CH_2OH$ is obtained, which is almost a food. The sugars are indeed real foods. The presence of the hydroxyl group may render substances more subject to the oxidative processes in the organism. Hydroxycaffeine 14 must be given in much larger doses than caffeine before caffeine action appears. It is apparently rapidly oxidized.

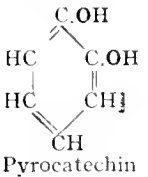


Caffeine

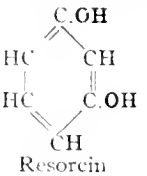


Hydroxycaffeine

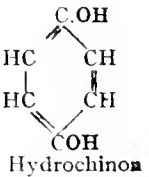
The phenolic hydroxyl, however, tends to increase the tetanizing effect of benzol. The addition of one or more additional hydroxyl groups weakens the tetanizing action, but increases toxicity in other directions. Here position in the nucleus is also a determining feature. The dioxy benzols all act on the spinal cord and produce clonic convulsions, the toxicity decreasing in the order given.



Pyrocatechin

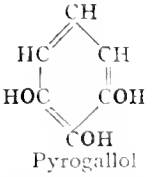


Resorcin

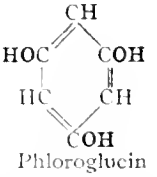


Hydrochinon

The trioxy benzols, pyrogallol, and phoroglucin are less toxic.



Pyrogallol

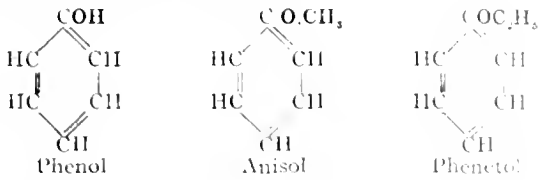


Phloroglucin

That the toxicity of these substances is intimately connected with the presence of the hydroxyl groups has been demonstrated by numerous observations. Stolnikow[15] showed that by the introduction of the indifferent sulphuric acid group in such substances as phenol, pyrogallol, and resorcin the resulting ether sulphuric acids were far less toxic than the phenols themselves.

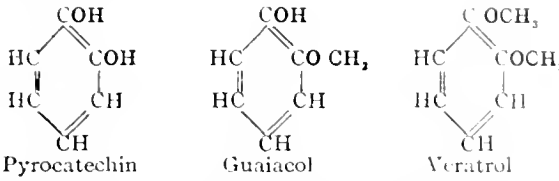
In the case of morphine and morphine ether sulphuric acid, the nature of the action was completely changed. The original narcotic action disappeared entirely and in very large doses a codeine effect was obtained. In like manner in anisol and phenetol the

methyl and ethyl ethers of phenol, the toxicity of phenol is greatly reduced.[16]



Phenol Anisol Phenetol

This is also well shown in the series pyrocatechin, guaiacol, and veratrol.



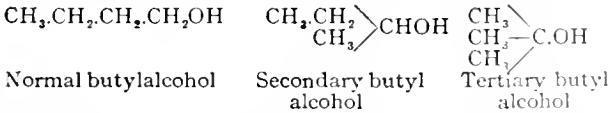
Pyrocatechin Guaiacol Veratrol

the toxicity diminishing in the order given with the covering of the hydroxyls by the methyl groups.

The phenolic hydroxyl in morphine is of considerable interest. Morphine is the only member of the opium alkaloids possessing a pronounced narcotic action. This action is to be ascribed to the phenolic hydroxyl group; for if this hydroxyl is covered by an alkyl group such as methyl, ethyl, and the like, the characteristic narcotic action almost entirely disappears and the tetanizing action of the rest of the molecule shown by the codeines becomes apparent.[17] The action is shifted from the brain centers to those of the cord.

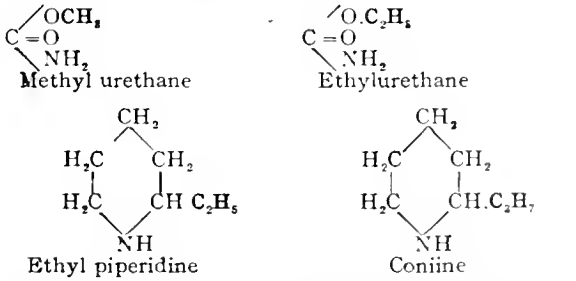
It is unlikely that any constant action can be attributed to the hydroxyl group as such. It would seem that the hydroxyl group is more the means of bringing a substance in contact with a particular tissue, and so affording the opportunity for the rest of the molecule to exert the action characteristic of it.

As regards the alkyl group such as methyl, ethyl, propyl, etc., it has been found that in combination with hydroxyl, as alcohols, the narcotic action of the original hydrocarbon is retained, the toxicity increasing with the molecular weight and the boiling point. In homologous series substances are more active the longer the carbon chain. Normal butyl alcohol is, therefore, more toxic than the tertiary alcohol. The tertiary alcohols exert the least narcotic effect, the secondary alcohols a greater, and the primary alcohols the greatest of all. This rule holds not only for alcohols but for other series as



Normal butylalcohol Secondary butyl alcohol Tertiary butyl alcohol

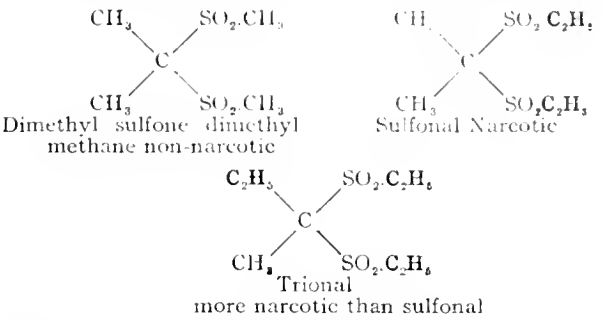
well. Ethyl urethane is more toxic than methyl urethane and propyl piperidine or coniine is twice as toxic as the ethyl compound.



Methyl urethane Ethylurethane

Ethyl piperidine Coniine

Of the alkyl groups the ethyl has proved of particular significance. Its presence in many substances with marked action on the central and peripheral nervous system have led many to ascribe to it particular neurotropic properties. The experiments of Baumann and Kast[18] in the sulfonal group demonstrated that the narcotic effect increased with

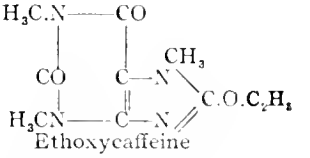


Dimethyl sulfone dimethyl methane non-narcotic

Sulfonal Narcotic

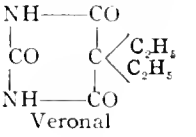
Trional more narcotic than sulfonal

the number of ethyl groups contained in the molecule and where the ethyl was replaced by other alkyl radicals the anesthetic power was lost. Ehrlich[19] has ascribed the universal use of alcoholic beverages and the persistent attempts to render them free from other higher alcohols (fusel oils) to the special property of the ethyl group. Ehrlich and Michaelis found that a diethyl safranin dye possessed the property similar to methylene blue of staining the nerve endings of surviving organs. When other safranin dyes were made minus the diethyl amido group, or in which the ethyls were replaced by methyls, this neurotropic property was entirely lost. In ethoxycaffeine[20]



Ethoxycaffeine

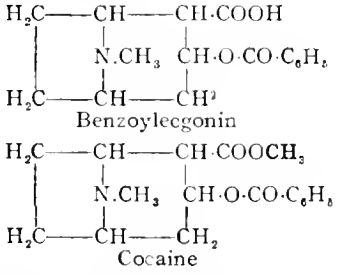
and veronal which is diethyl barbituric acid



Veronal

the marked narcotic action is attributable to the ethyl group.

In esters where the alkyl group is combined with a physiologically inactive acid the properties of the alkyl group are retained. In certain cases in which the inherent properties of the molecule may be hidden, as we shall later see by the presence of the carboxyl group, COOH, esterification will restore these inherent properties. In benzoyl ecgonin itself the inherent anesthetic property of the molecule is hidden by the free COOH present. The substance is twenty times less toxic than cocaine. When it is methylated cocaine results and the anesthetic properties appear.

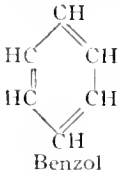


Benzoylecgonin

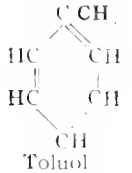
Cocaine

Alkyl groups entering into the aromatic nucleus effect considerably the original action. The activity

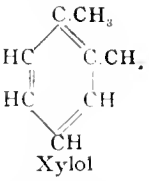
of benzol decreases with the introduction of methyl groups, so that the toxicity diminishes from benzol through toluol and the xylols to mesitylene.



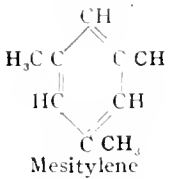
Benzol



Toluol



Xylol



Mesitylene

Introduction of the methyl group into the benzol nucleus increases the antiseptic power. The introduction of methyl or ethyl groups into ammonia diminishes its convulsing properties. In general, methylation on a nitrogen atom diminishes or removes entirely the toxicity of the original compound.

The entrance of chlorine into aliphatic substances increases in general the narcotic action. The toxic effect stands in direct relationship to the narcotic action. With the increase in the number of chlorine atoms the toxicity becomes greater. For instance, methylene chloride, CH_2Cl_2, is less toxic than chloroform, $CHCl_3$, and this again less so than carbontetrachloride, CCl_4.

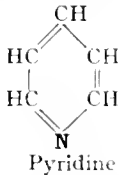
The introduction of chlorine into the benzol nucleus has but slight effect on its action. Benzol derivatives substituted by halogens in the nucleus are more strongly antiseptic than the mother substance. In general bromine substitution products in the aliphatic and aromatic series resemble the analogous chlorine derivatives. Organic iodine compounds differ from the other halogen compounds in being more antiseptic and less narcotic.

In regard to the action of the basic nitrogen containing radicals it may be said that the entrance of nitrogen as an amino group in aliphatic or aromatic compounds as well as the presence of nitrogen in cyclic bases may have a various pharmacological significance. The action depends mostly upon the nature of the rest of the molecule, upon the nature of the linking, and the valence of the nitrogen as well as the reactivity of the nitrogen containing group. Ammonia, the simplest of the series, aside from its irritating action has a tetanizing effect. If the hydrogens are replaced by methyl or ethyl groups, this action is gradually diminished so that the final product, trimethylamine, is without action. If an acid radical is introduced as in acetamid the substance is nearly or entirely without effect. Acetamid passes unchanged through the organism. Where nitrogens are joined together, as in hydrazine, a very toxic group is produced. Where they are joined together by a carbon chain, as in tetra and penta methylene diamine, they are comparatively harmless.

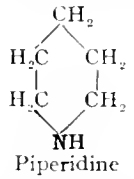
$NH_2.CH_2.CH_2.CH_2.CH_2.NH_2$ Tetra methylene diamine

$H_2N.NH_2$ Hydrazine

Aromatic amino compounds are of special interest because of their relation to the phenacetin series of antipyretics. In the union of the aromatic nucleus with the amido group, the ammonia action predominates. These substances may produce convulsions and paralyze the muscles and nerves. The substitution of simple elements like chlorine, bromine, etc., in the benzol nucleus of aromatic amido compounds changes but little the action. An alkyl group increases the action. Substitution in the amino group itself by alkyl radicals reduces the toxicity considerably. The aliphatic diamines are physiologically little active; on the other hand, the aromatic bases are extremely toxic, as, for example, toluylenediamine and the phenylenediamines. In general, substances which have a tertiary nitrogen, such as pyridine or its homologues, are but little toxic.



Pyridine



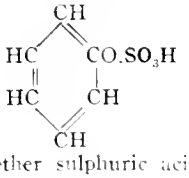
Piperidine

If by reduction to its hydro-base piperidine, the nitrogen is changed to an amid group, NH, a strongly toxic substance is produced. If the amid hydrogen is replaced by an alkyl group the substance again becomes inactive. If alkylation continues so that substituted ammonia bases are formed, a curarizing substance is obtained.

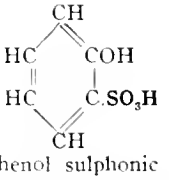
The nitro and nitroso groups possess little general significance other than that their introduction into compounds increases the toxicity. As aliphatic alkyl esters of nitrous acid their action is characterized by marked dilatation of the blood-vessels, the action decreasing from the maximum in the amyl ester down to the methyl ester which is least active.

The aldehyde group in the fatty series appears to possess narcotic properties as in acetaldehyde. To the aromatic aldehyde group but little significance can be attributed, due to its rapid oxidation to the acid.

The action of acid radicals such as the carboxyl and sulpho groups is one of the most interesting instances of the effect of groups. There are a large number of toxic substances against which the organism protects itself by conjugating them with glycocol, sulphuric acid, and glucuronic acid, the resulting substances being excreted as such. This detoxification is due to the entrance of the acid group into the molecule. This rule is pretty general so that if by chemical means we introduce into toxic substances a carboxyl or sulpho group the toxicity is greatly reduced, if not entirely removed. For instance, the conversion of phenol into the oxybenzoic acids removes almost entirely the toxicity of phenol. Phenol ether sulphuric acid[21] and phenol sulphonic acid are practically harmless.

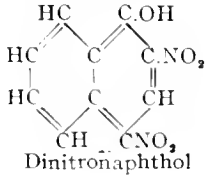


Phenol ether sulphuric acid



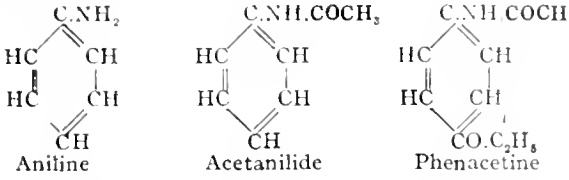
Phenol sulphonic acid

The formation of morphine ether sulfuric acid removes entirely its narcotic action and only in large doses is the codein effect characteristic of the rest of the molecule to be observed. Even the toxic action of the nitro group is antagonized as seen in the conversion of the very toxic Martius yellow or dinitronaphthol into the harmless sulphonic acid.



Dinitronaphthol

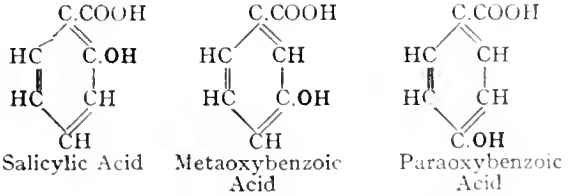
The relative toxicity of benzol, toluol and naphthalin and their carboxyl derivatives are further examples. The very toxic pyrocatechin and the nontoxic protocatechuic acid show this influence again and endless other examples might be cited. The entrance of acid radicals into aromatic amido compounds has been of particular therapeutic importance. The conversion of anilin into acetanilid or antifebrin removes to a great extent the harmful action of anilin upon the blood, without affecting its antipyretic properties. Phenacetin likewise belongs here.



Aniline Acetanilide Phenacetine

The presence of a double or triple bond in the molecule increases as a rule the toxicity. Allylalcohol,[22] $CH_2{=}CH.CH_2OH$, which is but an unsaturated propylalcohol, no longer possesses the characteristic narcotic properties of the alcohol group. Diiodoacetylene, $IC{\equiv}CI$, with a triple bond is very toxic; much more so than could be attributed to the iodine in it.

Among aromatic substances considerable differences are to be found in the action of isomers. The well known example of the differences in the action of salicylic acid which is orth-oxybenzoic acid and its inert isomeric oxybenzoic acids, may be mentioned.



Salicylic Acid Metaoxybenzoic Acid Paraoxybenzoic Acid

Although no general rule can be made, in the majority of instances the toxicity increases from the ortho through the meta to the para compound. This is shown by the isomeric nitro phenols, nitro toluols, brom toluols and toluidins. As regards toxicity there are, however, numerous examples in which either the ortho or the meta compounds exceed in toxicity. Among the alkaloids, position is likewise a determining feature in the action; for the shifting of a side chain from one position to another is accompanied by striking changes in the character or intensity of the action. Of a still greater significance are the differences presented in their behavior towards the organism of substances which have identical atomic groupings in the molecule but differ in the arrangement of these atoms or groups in space about one or more asymmetric carbon atoms. Differences in the action of such stereoisomeric substances were first observed by Pasteur. Various fungi, grown in media containing optically inactive tartaric acid, were found to render the solution levorotatory. The organism assimilated the dextro form leaving the other unavailable form intact. At that time he drew the correct conclusion that physiological action is dependent in some way upon the geometrical arrangement of atoms in space. Such observations were later continued by Fischer[23] in his classical studies in the sugar group. The glucosides of the hexoses were divided into two groups, one being cleaved by yeast invertase, the other by emulsin. Also those sugars only which possessed three or a multiple of three atoms of carbon would undergo alcoholic fermentation. From these results Fischer concluded that in order for an enzyme to act upon an optically active substance the configuration of the one must fit into the configuration of the other, just as a key fits in its lock. Experience with the intermediary products of proteins has consistently confirmed these views and many observations have been made of the behavior of optically active substances in the organism, which still further bear this out. When racemic mixtures of sugars or amino acids are fed to an animal it is found that under normal conditions the organism will burn the natural form, while that form not occurring in the animal tissues is excreted in the urine.

Among the alkaloids considerable differences have been observed in the pharmacological action of optical isomers. The isomers cinchonine and cinchonidine, quinine and quinidine, the hyoscyamines and atropine all show differences in the intensity and character of their action. Recently this has been demonstrated by Cushny[24] and Abderhalden[25] with adrenalin. The synthetic adrenalin is generally found to be less active than the natural product. After the successful cleavage of the synthetic preparation into its optically active antipodes, the dextro form was found to be comparatively inert the activity of the laevo form equaling that of the natural product. As the synthetic product is an equal mixture of the two forms, its smaller effectiveness was explained.

The Champetier de Ribes Balloon in Treatment of Vaginismus.—L. Funck-Brentano describes a new minor operation for vaginismus in extreme cases, in which even a touch on the hymen causes intense contraction. He anesthetizes the patient, places a balloon having a diameter of 5 or 6 cm. in the vagina, then inflates the balloon and on its surface excises the hymen entirely with scissors. Then he extracts the balloon and introduces a larger one. The larger balloons must be extracted slowly for fear of tearing the vagina.—*La Gynécologie.*

PELLAGRA.*

By M. M. SMITH, M.D.,

DALLAS, TEX.

MEDICAL DIRECTOR MODERN ORDER OF PRAETORIANS.

THE Chairman of the Association of Life Insurance Presidents at their Fifth Annual Meeting held in New York, December, 1911, said in his address, "These annual gatherings may be likened to a great ocean liner in port, coaling up; laying in store the material that creates propulsive power, such as will enable it to stand the strain and buffet the storms that beat against it, when it comes to the real work for which it is built. And so, laying up in store the advice, the suggestions, the admonitions, the knowledge and wisdom of generous helpers, we may confidently trust those who are in command to study the charts, to lay out the course, to start the enginery, and to put in operation all those practical appliances which will most economically and effectively produce the results for which this Association was devised." What was so beautifully expressed by President Hegeman will apply with equal force to this organization.

The time alloted me for this paper will not permit of a discussion of pellagra in its various phases and I shall confine myself to those phases of the subject, which are of the greatest interest to the Medical Directors of Life Insurance Companies.

Pellagra is a disease which has been prevalent in Europe for more than a century. Its increase in many sections attracted the attention of some of the leading physicians of the world. The disease was regarded as a national menace in Italy and strong prophylactic measures looking to its prevention were enacted. So great was its prevalence that at one time there were more than 100,000 cases in Italy alone, and the infected area was only a portion of that country. At the present time the disease is most prevalent in Northern and Central Italy, Southern Roumania, the Austrian Tyrol, Southeastern Hungary, Lower Egypt, and the Southeastern United States. In this country a few isolated cases were discovered and referred to in medical literature prior to 1907, but at that time, authentic cases were reported to exist in thirty-seven States. Through information obtained through general reading upon the subject, and a correspondence with the professors of the chair of practice of the medical colleges of the United States, the various boards of health, and physicians who have been coworkers, I am inclined to believe that at the present time there exist from ten to fifteen thousand cases of pellagra in the United States, these principally in the Southeastern States. The most malignant types of the disease have been found in large numbers in the insane asylums. There is no question but what the disease is rapidly increasing in this country to-day, and I can truthfully say to an alarming extent. One writer of prominence (Dr. E. H. Martin, Hot Springs, Ark.) used the following language, "The importance of this subject may be realized when we consider there have been probably 100,000 cases of pellagra in the United States during the summer, and that we may expect possibly one-half million new cases next spring." This statement was made in a paper read at the Medical Section of the Southwest Medical Association in Oklahoma City, October, 1911. I am not, however, as much a pessimist concerning the disease as Dr. Martin.

Etiology.—The cause of the disease is not definitely known at this time. The general belief that poisoning by the use of Indian corn as an article of diet has been the theory as to its cause for the past century and this theory is particularly held in Italy where the disease has been most prevalent.

Another theory advanced in 1903 by Sambon that the disease is caused by the bites of the Simulium fly. This is of recent origin and is unquestionably more acceptable as an explanation for the cause of the disease and its confinement to certain localities.

Again, the theory of Allessandrini, advanced in 1910, is that it is a parasitic disease caused by a water-borne nematode worm. Many other theories have recently been advanced as to the cause of the disease. Some hold that it is a form of amebiasis; others that it is caused by the use of cotton-seed oil and other semi-drying oils, as articles of diet.

I shall not attempt to discuss these various theories, but merely mention them to show that, although the disease has existed in thousands of cases for more than a century in Europe and now in America, at the present time no definite and positive cause for it is known.

Diagnosis.—The diagnosis of pellagra in well-marked cases, where the skin manifestations and the constitutional phenomena are in evidence or the so-called pellagrous triad of erythema, nervous, and digestive disturbances are present should cause no difficulty; but it is a well-known fact that the disease is often not diagnosed by men who are recognized competent diagnosticians because of the lack of knowledge concerning its symptomatology, and the inattention to the literature of the current medical journals and public health reports of today. An early diagnosis where there is merely the first indications of the disease would necessarily be a difficult one, especially with those who are inexperienced with the disease.

Prognosis.—The experience with the disease in America shows that the mortality rate is very much higher in the United States than in Europe. In fact, the type of the disease seems to be much more severe here than in the Italian pellagra of today. The death rate of pellagra at the present time in the United States is probably from 25 to 33 1/3 per cent.; this includes the asylum cases. I should say with an early recognition and the most appropriate treatment of cases, extending over a long period of time, there is a very small mortality, but with the far advanced cases, particularly those found in the insane asylums, and in the typhoid type of the disease, the mortality is exceedingly high. The death rate is probably double in the United States what it is in other countries. It seems to be one of the characteristics of the disease for the prognosis to improve gradually with its continued existence. Whether this is due to a partial immunity being established, an attenuated virus as a result, or whether the mortality is reduced more on account of the physicians' experience with its symptomatology and treatment, whereby early diagnoses are made and the most appropriate treatment given, I cannot say.

Treatment.—At the present time there is no definite, specific treatment of pellagra. Nevertheless, much has been done in the last few years by physicians in various portions of the United States, particularly in the pellagra sections of the country, in outlining a general plan of treatment. This I shall

*Read by invitation at the meeting of the Medical Section of the American Life Convention, held in San Antonio, Texas, February 28-29 and March 1, 1912.

not discuss in detail, but simply say that the most successful plan at the present time is the regulation of diet, with wholesome surroundings, climatic change, if possible, and a suitable preparation of arsenic in the form of atoxyl, soamin, salvarsan, or other forms. Transfusion, serum treatment, and other plans have been used.

With the above-mentioned facts before us, namely, (1) the prevalence and rapid increase of pellagra in the United States; (2) that this is a disease the cause of which is not definitely known; (3) that it is a condition that is not diagnosed early; and (4) that it is a disease that has a very high death rate, should make us, as medical directors, give the problem serious consideration as we are the door-keepers, as it were, to the great savings banks represented in the form of life insurance companies.

What are some of the things which might lead to a successful solution of this impending danger? First, pellagra is a national health problem in the United States at the present time, hence it should receive the serious consideration of the National Health Department, including the boards of health of the respective states where it exists. Concerted action should be taken by both the National and State Health Departments looking to legislative enactments and appropriations sufficient to furnish money to carry on proper investigations where pellagra is present to any extent and where extensive detailed work may be done looking to the study of the cause of the disease, its prevention, etc.

Secondly, pellagra should be made a reportable disease, with a statute requiring all cases to be reported to the proper health officers, thus furnishing vital statistics and affording an opportunity for scientific investigators to ascertain the complete case-histories and such other information as may be desired which will aid very materially in ascertaining the cause of the disease, its prevention and the most successful treatment.

Thirdly, an educational campaign should be waged by the National Government, the respective State Health Departments where the disease exists, including the county and city health officers, for the education of the medical profession at large, so that they may be able to recognize the disease in its earliest stages and be prepared to administer the best possible treatment. Such educational work can be materially improved by well-arranged clinics through the various medical associations and schools and the presentation of suitable papers and their discussion in such organizations. In addition to these clinics, lectures should be held and wholesome literature for the people in general should be distributed so that the people may realize the value of healthy surroundings, the need of wholesome foods, the proper observance of rules of bathing, strict vigilance as to quality of corn preparations they eat, suitable screening for places of residence, and such other educational steps as will tend to better their condition, particularly of the poorer classes where the disease exacts its greatest toll.

Conclusion.—In conclusion, gentlemen, I have briefly referred to the uncertainty of the cause, the varied symptomatology, the grave mortality and the prevalence of this disease with its rapid increase in this country for the purpose of impressing upon you the importance and necessity of active work being done throughout the pellagra portions of the United States especially, so that we may not be in a state of unpreparedness in case of a real epidemic of the disease, but far more important it is to prevent such an epidemic, rather than to suffer its ravages.

In passing I desire to say that the company with which I am connected has paid four death claims in the past two years caused by pellagra and I do not doubt that other companies represented here have had similar experiences.

I believe the local medical examiner, who has no speaking acquaintances with this disease, might conscientiously recommend as a first-class risk for insurance, a comparatively early case of pellagra, should such a case undergo examination during the interval of apparent good health, as such periods are very common with the disease. By the dissemination of this knowledge among the local medical examiners of the various insurance companies, with the importance of the early recognition of the premonitory symptoms of pellagra stressed, as it were, thereby pointing to its early recognition, might be the means of preventing a large percentage of such cases being accepted as insurance risks.

As the conservation of the public health is of very great importance to all insurance companies, it behooves us as medical directors to bring before the management of our companies the importance of concerted action looking to more active steps being taken in a united way looking to the accomplishment of the things I have crudely suggested in this paper, which apply especially to pellagra; but will aid very materially in preventing the spread of other diseases.

OVERWORK AND FATIGUE IN RELATION TO NERVOUS PROSTRATION.*

By EDWARD LIVINGSTON HUNT, M.D.,

NEW YORK.

INSTRUCTOR IN NEUROLOGY, COLUMBIA UNIVERSITY; ASSOCIATE CONSULTING NEUROLOGIST, ST. LUKE'S HOSPITAL; CONSULTING NEUROLOGIST, LINCOLN HOSPITAL; NEUROLOGIST TO PENITENTIARY AND WORKHOUSE AND N. Y. CITY HOME FOR THE AGED; ASSISTANT CHIEF NEUROLOGICAL DEPT., VANDERBILT CLINIC.

Nervous prostration means nervous collapse. It is a condition to which the Hebrew, the Slav, and the Scandinavian are particularly liable—men and women in about equal proportion. It is a disease of early and middle life, seldom occurring before twenty or after fifty. It, therefore, comes at that period of life when the energies, the producing capacity, and the struggle for existence are greatest. Its coming is not abrupt but is heralded by many and familiar signs.

The danger signals which foretell a nervous breakdown are irritability, fault finding, and peevishness. The patient becomes suspicious and introspective. His work is done with less care and greater friction; it goes slower and its character deteriorates. The power to concentrate is diminished. He complains of headache, giddiness, and dyspepsia. Fears and anxieties appear: confusion and indecision complete the picture.

There are many types of nervous collapse, according as to which part of the nervous system is most affected. One patient may complain of pains, another of digestive disturbances, a third of apprehension and loss of assurance, a fourth of depression and so on, each of itself a symptom betokening loss of control and a nervous mechanism which "Like sweet bells is jangled out of tune, and harsh."

The nervous mechanism is a wonderfully planned and exceedingly delicate organism. Its adjustment is very fine. Little things, seemingly of no importance, affect it tremendously. A delicate and highly

*Read at a meeting of the Public Health Education Committee of the Medical Society of the County of New York, March 20, 1912.

organized nervous system is impaired by any excess. A room of bad air, an abrupt change of temperature, or an overdose of alcohol or of food may and can disturb its careful and steady workings. On the other hand too close observation and a too ready interpretation of the multitudinous signs, which appear in a nervous patient, may also materially disturb its workings.

The causes of nervous prostration are many and various. Of the predisposing causes the two most important are defective heredity and civilization. Of the exciting causes I might enumerate excesses, poisons, worry, competition, city life, lack of exercise, poor food, bad air.

Nervous prostration teaches us many things. It teaches us that we do not come into this world equal, that our attainments are not the same, and that as we advance our development is not similar; it teaches us that each man is a law unto himself; it teaches us that in many our ambitions must have limitations; it teaches us that if we become prodigal of our nervous energy we shall pay and pay heavily; finally it teaches us that we must have regard for the laws of physiology and of reason.

Nervous prostration is an overdraft; it means that you have strained the nervous cells, not to the limit, but beyond the limit; it means that you have pulled the walls of the physical house down about your head; it means panic. As the nervous system is intimately and closely allied to every other structure of the body it means that the ruin is widespread and the symptoms legion.

The great excess of the present generation is overwork. In this respect without doubt America leads all nations. Mills found that the average length of life in 105 overworked American public men was only fifty-eight, whereas in an even larger number of members of Parliament the average was sixty-eight. The American is apt to have completed his work before the Englishman begins to reap his reward.

Women are equally as susceptible to overwork as men. It is by no means an uncommon thing here in New York to hear women say that they have no time to accomplish all that they wish. Their varieties of interests are great and their understandings far exceed their nervous strength. Women are more apt to feel the effects of their overwork than men, partly because they possess more susceptible and more delicate temperaments and partly because they are more apt to neglect food and exercise. The society woman rarely exercises enough, the working woman rarely eats enough, neither gets enough of air and outdoor life.

Overwork was considered a virtue; now it is known to be a vice. It is recognized as a debauch—one to be shunned equally with those of alcohol, of opium, of meat, and of excessive pleasure. It is just as ferocious; it brings in its train just as many ills. Overwork is contagious. The very air of New York breathes and burns overwork. The wife of an overworked man is very apt to be driven from sheer lack of occupation and companionship into undertaking more and greater problems than are compatible with her strength. The high cost of living, the desire to emulate one's neighbors, and the wish for luxuries beyond their grasp are important factors in bringing about overwork in both the sexes. The hold which pleasure has on many precipitates overwork. The woman who is the breadwinner feels the need of relaxation and pleasure. To obtain it she has to make unusual and undue demands upon her strength. This is a form of overwork.

Overwork pleases because it stimulates; it entices because it leads to power; it entrances because it beckons fame. Regard it however from the opposite point of view. It enslaves the worker; it narrows his field of vision, augments his egotism, and deprives his family and friends of the pleasures of his society and of the benefit of his experience. It is a selfish fashion and one which inevitably leads to destruction. It makes a man unfit to live with and it makes him unmindful of his duties as a man, a citizen, and a patriot.

In saying these very hard facts about overwork I do not forget the old maxim which we have all learned in our childhood. I mean that very old saying that work hurts no man. It shall not be forgotten, but with it, hand in hand, should go the modern saying that overwork hurts every man. A quarter of a century ago Dr. Weir Mitchell in a classical book struck the keynote of this situation when he said, "Wear is use; tear is abuse."

Every man should work, but no man should overwork. How are we to discriminate between the two? Where draw the line? What is to be the measure of how much work a man should do? What are the indications that we have overstepped the boundary line of the possible work and have crossed into the region of the impossible overwork? In short, what is work and what is overwork?

There is no standard. There is neither physical nor mental guidepost which can mark for us the passage from work to overwork. In this respect every man is a law unto himself. Each constitution has to be considered on its own merits. What is one man's work is another man's overwork. Just as a child requires a smaller dose of medicine than a man, so it is in work. The dose of work must be regulated according to the needs, the requirements, and the abilities of the worker. It is well to bear this in mind. Neither a young nor an old man can exhibit the same energy, the same force, nor the same strength as one who is of mature years and in his prime. These facts are too often lost sight of and too hastily thrust aside. Either man or woman who has undertaken a task, who has entered into a struggle, should carefully consider his equipment and especially his nervous equipment. It was Our Lord himself who said, "Which of you, intending to build a tower, sitteth not down first, and counteth the cost, whether he have sufficient to finish it?"

Old as the hills, no better words than these could be brought to illustrate my meaning. Sit down first and count the cost—the cost of the nervous energy. Balance your nervous bank account as often as you balance your financial bank account. It is of much more importance to you. A surplus of nervous energy is the greatest asset you can have—so long as you do not speculate with it. Be satisfied with a fair return. Don't expect a large interest. Remember that a large return is the price of danger.

I once had a patient who told me that on one occasion in his life he had spent two whole days and two whole nights in his law office dictating to relays of stenographers. All the meals had been sent in from neighboring restaurants; tobacco, coffee, and work had filled up the forty-eight hours. Was this ennobling, was this worthy of a fine man? but let me tell you of the sequel to this debauch. A few weeks later he contracted a simple condition—a condition which you and I could readily have thrown aside. So low, however, were his vital powers and so abused and devastated was his nervous system that he developed a delirious and delusional state; this simple little condition turned into a protracted

and prolonged illness, which finally killed the man. Overwork not only injures the worker but it injures posterity. It not only deteriorates the worker but it deteriorates the work.

The woman who, in addition to her regular duties as the head of a modern New York house and the mother of several children, undertakes to keep up a large acquaintance, to join card parties, to do some studying, and then entertain and be entertained, is approaching the line of overwork. The home is a place of rest, and relaxation much more to the man than the woman. He is constantly shielded; she is constantly the shield. She therefore rarely finds it as easy to obtain rest at home as he does. Few women realize this, and therefore few systematically arrange or find it possible to arrange to rest at a time when it is most beneficial and most lasting. To rest, one must be free from cares, interruptions, and noise.

Let me cite one other instance of an overworked man. Somewhere here in New York there lives an ambitious and very hard working lawyer. He gets home at 7:00, swallows his dinner, and shortly after 8:00 he is in his study once more hard at work. Here he stays, writing briefs, studying cases, and outlining arguments until midnight. This is a nightly occurrence. I ask you is not that man overworking? Is he not injuring the unborn and is he giving his clients the best that is in him?

Overwork injures not only the nervous system but also the physical. The overworked brain is flushed with blood, the blood vessels are distended, and the delicate arteries continualy and constantly are put to their utmost. The artery is injured and in time there develops that bête noir of the middle-aged man—endarteritis or what you call a thickening of the arteries. From this result, as you know, depression, anxiety, melancholia, and a host of phobias.

There is a tendency in the schools to overwork. Children are driven. Few principals ever consider this; how can a class of twenty boys do the same amount of work when half claim their parentage from the peasant stock and half from overworked fathers? So then avoid overwork. Find the number of foot pounds that you can raise and don't raise one more. Get your gauge.

There is a form of overwork, exceedingly common and exceedingly disastrous—one which equally accompanies great intellectual labors and minor tasks. I allude to *worry*. When we medical men speak of the workings of the brain we make use of a term both expressive and characteristic. It is to cerebrate. To cerebrate means to think, to reason, and to reach conclusions; it means to concentrate and to work hard. To think then is to cerebrate and to worry is to cerebrate intensely. Worry is overwork of the most disastrous kind; it means to drive the mental machinery at an unreasonable and dangerous rate. Worry gives the brain no rest but rather keeps the delicate cells in constant and continuous action. Work is wear; worry is tear. Overwork, mental strain, and worry lead to a diminution of nerve force and to a destruction of nerve energy; they invite a prostration of the vital forces and cause a degeneracy of the blood vessels of the brain.

Exhaustion, another name for fatigue, may show itself either in the form of physical collapse, so that the patient lacks resistance, and becoming anemic and run down, falls a prey to any and every little ailment or in the form of mental collapse. An exhausted brain then gives way to depression, to fears, and to anxiety.

Exhaustion may be due to disease or to excess. It may follow too little or too much food. It may be the result of too much brain work and too little physical exercise or *vice versa*. It may come as the result of too great concentration in one particular direction. It may follow too much pleasure or result from bad air, alcohol, or worry.

The vast majority of nervous breakdowns are avoidable; they are the result of our own excesses and of the disregard which we show toward the ordinary laws of health and hygiene; they are the results of the tremendous demands which are made upon us by modern life; they are the results of the strenuous life.

How then can we who live in a big and busy city with the telephone and the automobile hope to escape this fate? What course should we follow so that we can still fill our niche in the work of every day life and fill it profitably, advantageously, and without danger? We should cultivate in all things moderation. We should be masters of ourselves. We should follow strictly the rules of health. Exercise, baths, and fresh air should be just as important as simple and good food. We should strive to expend as little energy as possible. We should avoid large public assemblages where the air is bad and the crowds weary us. We should not always strive and struggle to do something new and something different. We should cultivate contentment.

When you are thoroughly tired and begin to feel that peculiar sense of lassitude and exhaustion creep over you then it is time to have a change of work. I have known men who could work for a very long time so long as they constantly changed the character of their work. Give one set of cells a rest and utilize another. Have a variety of interests, keep abreast of the times, know a little about politics, art, and books. Have a hobby. Everyone should have some one thing in which he can interest himself and to which he can turn—some channel in which he can divert his energy, so that he can free it from the well-worn path of the daily labor.

Another lesson which we all need to learn is to think of our business only in business hours. When you leave the shop leave your business, when you lock your desk lock your thoughts. Have an hour in the day which belongs to your children. Spend it with them. It will help them and it will help you. Have something which will be of interest and pleasure to your children as well as of benefit to yourself. It may only be a romp in an improvised gymnasium, it may be a dip in the ocean, it may be a walk home from the station. If you can't do anything better, play bear with your boy. If you have no boy play bear anyhow.

The tendency of the business and professional men of the present day is too narrow. Their interests are too largely centered on their own advancement with a total disregard of everything else and everybody else.

When you are tired, when you are weary, and when things have gone wrong don't lie down with a book which you think you are reading and enjoying, but get out in the fresh air under the blue sky, play a game of tennis, ride a horse, or take a long walk. You will return refreshed, invigorated, and with renewed energy. Exercise makes energy. Oxygen gives force.

Never let your brain rehearse the mistakes and failures of the day. In the language of the nursery, don't cry over spilt milk.

Women should realize the great importance of being out in the fresh air. Man from the nature of

his life has to go out every morning and has to take a certain amount of exercise. Women do not get out enough and do not exercise enough. Every well woman should make it a rule to walk two miles daily. The seamstress, the school teacher, and the shop girl especially need long walks, good food, and fresh air.

Learn to sleep. Both men and women should spend more time in bed. Here in New York we do not sleep enough. There is nothing that will repair tired and jaded nerves quicker and more lastingly than a long unbroken sleep. I have known patients who complained of irritability, brain fag, and exhaustion, who when put to bed would sleep almost continuously for three or four days and nights. Sleep is of great value, it starts us anew, it supplies energy, it winds up the physical clock. It is a panacea for all ills. There is no greater remedy for worry than this same sleep.

"— the innocent sleep;
"Sleep, that knits up the ravell'd sleave of care,
"The death of each day's life, sore labours bath,
"Balm of hurt minds, great nature's second course,
"Chief nourisher in life's feast."

Avoid alcohol. It doesn't stimulate, it depresses. Avoid fatigue, it, too, depresses. Avoid large public assemblages. The air is bad and contact with great numbers is great wear.

Don't overeat, and above all don't overeat meat. If you wish to eat a great deal of meat then you must take a great deal of exercise. Earn your roast beef.

Don't hurry. Don't worry. As Dr. Mitchell puts it admirably in his novel, the "Red City": "Learn the lesson of the midyears of life—to be of all thought the despot."

INJECTION OF PARAFFIN FOR INCONTINENCE OF URINE FOLLOWING TRAUMA TO THE URETHRA.

By EUGENE H. EISING, M.D.,
NEW YORK,
ADJUNCT SURGEON, MOUNT SINAI HOSPITAL.

The use of paraffin in surgery since its introduction by Gersuny about 15 years ago has, if nit fallen out of use, at least found narrow limits for its employment. In its earliest days it was used for many conditions for which it was entirely unsuited and beside meeting with failure at times invoked complications more or less disastrous. It is in connection with the intractible symptom of dribbling of urine in the female that I would revive interest in the injection of paraffin. From to time to time the cure of these cases has appeared in medical literature following the injection of paraffin, after operative methods have failed. It is to this list of cases that I would add two of my own.

The type of incontinence referred to is a relative one, that is the incontinence is not complete. There are usually to be found several ounces of urine in the bladder. The cause of the condition is invariably due to the mechanical effects of childbearing upon the surrounding muscular coats of the urethra, which is left in a relaxed condition. The symptom usually does not make itself manifest until the patient assumes the erect posture. Cystoscopically the bladder is found entirely normal. If the bladder is moderately distended with fluid, the fluid is retained until the erect posture is again assumed, when the dribbling recommences. The increase in the intraabdominal pressure caused by the corset increases the incontinence. Relief is sought from this distressing condition and after the nonoperative methods are exhausted, surgical means are usually pursued. The surgical measure is usually selected according to the exigencies of the case, with the view of restoring normal conditions and with the hope that the troublesome symptom will remain away. A disappointment usually follows. Or, as in one of my cases in which a deliberate dissection of the urethra through the vaginal wall was made and lateral plications were made over the urethra, a functional failure ensues.

Based on an experience of only two cases and from a citation of the literature, I would suggest the submucous injection of paraffin as the method of first recourse giving the greatest probability of cure. Herewith are reported the two cases:

Case I.—Mrs. D. J., age 36 years, mother of three children. Incontinence followed birth of first child, 14 years ago. Was treated at beginning with bladder irrigations, then followed a long period of neglect for about 10 years. The condition became aggravated and she was operated upon twice in the West. Following these operations the dribbling remained constant except when the patient occupied the horizontal position. The bladder was always found to contain several ounces of urine. In May, 1911, an operation was performed through a vertical incision in the vagina overlying the urethra. Transverse plications were made so as to narrow the lumen of the urethra for most of its length and mucous membrane was closed over it. The immediate result seemed good and the incontinence remained controlled for six weeks. Following this, although somewhat improved, the dribbling continued. In October, 1911, one injection of paraffin was made parallel to and along the urethra. The injection was followed by considerable reaction. The pain lasted one week and there was some swelling. From the very beginning the dribbling has ceased and the bladder control is now perfect.

Case II.—Mrs. R. M., age 38 years, mother of one child, 8 years old. Dribbling of urine has been constant since the birth of the child. The uterus was found large and retroflexed and was thought to be the cause of the incontinence. In January, 1911, ventrosuspension was done. After the operation all seemed well until the patient began to wear the corset four weeks after the operation. Incontinence is present only after the application of the corset. Three injections of paraffin were made, the first two proving only partially effective. The third injection was followed by cessation of the dribbling and perfect bladder control.

The purpose of this report is to emphasize the prompt and excellent results following this simple procedure. The paraffin used in these two cases was of the ordinary commercial type, no admixture of soft paraffin being used. The use of a special syringe is not necessary, if sterilized chamois gloves be worn so as to permit of the handling of the syringe while it is hot.

Alimentary Anaphylaxis.—E. Lesné and L. Dreyfus find that this condition occurs most frequently among infants who have had previous digestive troubles. The alimentary canal has the power to a certain extent of neutralizing the toxic effects of the albuminoids. The authors believe that pepsin and pancreatin also have this effect. They therefore advocate the administration of these ferments as a means of preventing anaphylaxis.—*Le Bulletin Médical.*

PURE AIR BY DIFFUSION.

By JOHN F. LOCKWOOD, M.D.,

KANSAS CITY, MO.

We use natural gas as a fuel and for lighting purposes. There is little or no odor about our natural gas, and it is therefore not discoverable by the sense of smell when it happens to escape into the living apartments.

Last night the gas in our residence was lit in the upper hall, which communicates freely with the sleeping rooms. The gas pressure lowered and the jet went out unnoticed by us. Later, as is usual after everybody has cooked the evening meal, the gas pressure rose and all night long the gas poured into the sleeping rooms. The family slept in these rooms and passed the night quite comfortably. It was at 5 A. M. that we awoke and heard a roaring. It did not sound like steam from the steam radiators, so we arose to investigate. Then it was that we discovered that gas had been escaping all night long. When we realized that we had been safely delivered from what might have been a case of wholesale methane poisoning we began to praise the bridge that had brought us over. Let us here deliberately detail to the reader the "bridge." Please patiently follow:

Last fall, as cold weather began, we put into practice the following scheme for ventilating the sleeping rooms: It consists of providing each bedroom with a yard square of "gills." We call them gills because of their similarity of purpose with the gills of a fish—*supplying oxygen*. One window in each bedroom is selected and the lower half is fitted with a light frame (or the summer screen may be used) covered with 6½ oz. drill or muslin sheeting. This forms the "gills." Now for the modus operandi: In the summer time when the temperature of the air is such that drafts are not dangerous we have no trouble in getting the right quality of air to breathe, but when the cold weather comes we are driven indoors and in anticipation of sudden cold snaps we seal our houses, filling cracks and crannies until not a breath of fresh air can enter. We have two reasons for doing this: One is to prevent cold drafts striking us, and another and principal reason, it may be, is to economize in fuel.

In sealed houses in winter we breathe and rebreathe the same air and each time we inspire it we rob it the more of its oxygen and laden it the more with carbon dioxide.

When one retires to sleep in a pent-up atmosphere, vitiating it more and more each hour, toward morning one feels the need of more covers, for the feet are cold. Why? Oxygen which unites with the fat in the blood and thus by combustion warms the body is much exhausted from the sleeping apartment, and so the morning finds the sleeper chilly, not rested, not refreshed, not repaired; the head aches, there are malaise, stupor, and a disinclination to begin the day. Now had the same time been spent in a canvas inclosure the air would have been *continuously replete* with that life-giving quality—oxygen. Such environment tends to keep the atmospheres equal or even in quality.

Air is a mixture, not a chemical compound; therefore to rob it of oxygen does not disintegrate it, but only lessens its life-sustaining quality.

	Inspired Air. Per cent.	Expired Air. Per cent.
Oxygen	21	16.6
Nitrogen	79	79
Carbon dioxide	.04	4.4

With each inspiration fully one-fifth of the oxygen diffuses into the blood. Do we know this to be true experimentally? We surely do. Herein is a practical demonstration of a gas *diffused* into a liquid through a moist intercepting membrane (the wall of the blood vessel). How rapid the process must be that it should be performed between the acts of inspiration and expiration! Patiently consider with me the steps: When we inbreathe the air tubes, terminating in blind ends, expand, enlarge, the residual air in the lungs retires into these blind ends followed in by the tidal air, the oxygen from the tidal air leaps into the residual air and on into the blood through the moist membrane (blood container), changing the blood from a purple to a bright scarlet, from the venous to the arterial state. This is called oxidation.

This process is almost instantaneous, and yet it is performed where the intercepting membrane is of so dense a structure that it will retain a pulsating stream of blood. Surely it is axiomatic that oxygen diffuses faster in air than in liquid.

May we lay alongside of the above detailed process another similar process: That of air purified by *diffusion* through a septum of porous cloth: that of a canvas inclosure—a house tent for a consumptive, it may be. Conceive with us the situation. Surrounding this canvas inclosure is a great reservoir of pure free air, the inside air is being depleted of its oxygen and vitiated with carbon dioxide by the indwellers, but the two atmospheres are in contact through the meshes of the cloth. These atmospheres have easy access to one another for the process of diffusion of their gases. This tireless automatic process is keeping the inside atmosphere like the outside up to its full quota of oxygen (one-fifth) by *diffusion*.

"Gases are to each other as a vacuum" is a familiar rule in physics. It is the application of this rule that saved the household from suffocation when the natural gas was poured into the sleeping apartments all night long and yet it was *diffused* out through the muslin-covered window openings and that so rapidly that it did not interfere with reparative sleep.

We would impress upon the reader that though this process is invisible, it is none the less effective. We believe because it is invisible it is not appreciated as it should be. We have seen the brightest patients in hospitals where much of the window space was (intentionally) covered with muslin, replacing the glass. The most cheerful children in a child's ward equipped extensively with these "gills." And why not?

A young lady patient with heart disease (dyspnea) thought it was draft fanning her face that rescued her, but she was thoroughly calmed all night long with "gills" in her bedroom window (and no drafts). The oxygen was supplied to her in proper proportions.

Does not the very use we put pure oxygen gas to in emergencies bespeak a place for our process—pure air by diffusion? Give pure oxygen gas to the suffocated pneumonic patient. Give pure air by diffusion to the consumptive twenty-four hours out of every twenty-four hours and he is gradually restored to a life of usefulness.

ANNUAL REPORT OF THE PUBLIC HEALTH AND MARINE HOSPITAL SERVICE

PERHAPS in no country is there an institution which has a scope of duties as great as that of the United States Public Health and Marine Hospital Service. Among these duties are scientific research and sanitation, the supervision of foreign and insular quarantine, immigration and interstate quarantine, and the preparation of sanitary reports and statistics. There is also a bureau having charge of the personnel and accounts of the service and miscellaneous matters. Each of these divisions is in charge of a medical officer. By means of special bureau regulations the several functions of these divisions are coordinated and their operations brought under the direct personal supervision of the surgeon-general. That all of these divisions work harmoniously is obvious to one who has a knowledge of what has been done by the service as a whole. It also emphasizes a fact already well known, that the average ability and capacity for work of the members of the service are of a high order. The report for the year ended June 30, 1911, contains a fund of valuable information. The report fills more than 300 pages so that only a cursory consideration of its more salient features is possible.

With regard to scientific research and sanitation it is stated that some of the investigations begun in previous years have been completed. Conspicuous among these have been the studies into the origin and prevalence of typhoid fever in the District of Columbia. It is of interest to note that the authority of Congress has been obtained to admit to Marine Hospitals for purpose of scientific study a limited number of cases of contagious and infectious diseases. Thus, at Wilmington, N. C., this provision has enabled the Marine Hospital staff to carry on investigations into the intestinal parasites of man, and similarly at Savannah, Ga., cases of pellagra have been carefully studied. Attention is drawn to the insufficiency of funds provided for the maintenance of the Hygienic Laboratory and it is properly urged that adequate provision should also be made for the special investigation of typhoid fever, tuberculosis, and pellagra. The last-named disease, particularly, threatens to become a national calamity. According to a conservative estimate there have been 25,000 cases of pellagra in the United States since 1907, when the disease began to attract attention.

During the fiscal year the service has inspected a total of 15,160 vessels at the domestic and insular quarantine stations and at foreign ports. The widespread epidemic of cholera which prevailed in Russia and Italy during the fall of 1910 and summer of 1911 necessitated the greatest vigilance on the part of the officers of the service and subjected its machinery to considerable strain. Fortunately the stringent measures resorted to had the desired effect of keeping cholera out of this country. The efforts of the service to guard the public have been especially noticeable in the Philippine Islands. In spite of the nearness of these islands to many infected foreign ports, and the almost daily arrival of vessels from such ports, the quarantine service has proved an effectual barrier against the entrance of disease. Indeed, the results attained with the aid of the military and civil health authorities in cleaning up the cities of the Philippine Islands, may be justly compared with the sanitary work done in Panama and Cuba. Universal vaccination has practically eradicated smallpox in the Philippine Islands. This disease is still unduly prevalent in the United States. The greatest numbers of cases reported during 1910 were in North Carolina, Texas, Michigan, Oklahoma, and Kansas. In Quebec the spread of smallpox has been shown to be almost wholly due to the neglect of vaccination and to the carelessness of the population with respect of mild cases. Probably a similar situation exists in this country and it is possible that only a rude awakening will dispel the prevailing belief that smallpox has lost its virulence and is not to be dreaded.

The medical inspection of immigrants has entailed considerable labor and has demanded not only expert medical knowledge but also tact and discrimination. During the past year 26 commissioned officers and 51 acting assistant surgeons were assigned to this work exclusively. During the fiscal year ended June 30, 1911, 1,098,809 immigrants were examined by medical officers of the service in regard to physical and mental fitness to enter the United States and its dependencies, Porto Rico and Hawaii.

The report records the endeavor of a particularly able and earnest group of men in safeguarding the health of the country and should commend itself to the consideration of all thoughtful citizens. Three thoughts are suggested by its study: First, that Congress should no longer endanger the permanence of the present high standard of efficiency by delaying the passage of the bill raising the pay of the officer of the service. Second, that when the Department of Public Health is established it should be built up around the Marine-Hospital Service as a nucleus, and should be, as is this service, a purely medical and sanitary institution, free from any political appointments. And third, that the quarantine service at New York and the few other places where the anomaly of a State or municipal quarantine still exists, should without delay be placed under the care of this body of trained sanitarians; the country would profit by freedom from the danger of imported epidemics and the State of New York would be spared a heavy expense.

THE TOXIC FACTOR IN TOBACCO.

The subject of tobacco smoking is one about which various expert and popular opinions have been formed, though generally these ideas have been almost as nebulous as the fumes of the seductive weed. Few will fail to recall the lurid picture of the baneful effects of cigarette smoking painted by the preceptors of youth, and the opinions of one's maturer years are largely tinctured with these early impressions, many of which were perhaps decidedly painful. At any rate there is at present lacking any exact knowledge of the relative toxicity of the various forms of tobacco and of the different methods of smoking it. For this reason the investigations recently conducted in the *Lancet* laboratory and reported in that journal of April 6, 1912, merit attention.

The objects of these investigations were to devise new and more accurate methods of estimating the amount of nicotine contained in tobacco-leaf; to determine the relationship of the true amount of nicotine in any tobacco to that in the smoke produced from that tobacco; and to determine whether this relationship is modified by the way in which the tobacco is smoked—in the pipe, cigarette, and cigar.

In regard to the first of these objects it is noted that the established methods of determining the percentage of nicotine have been vitiated by the fact that it has been difficult to separate ammoniacal compounds from the alkaloidal base. Without detailing the steps of the newer method evolved in the *Lancet* laboratory, it may be stated that this method eliminates the above difficulty, with the result that the amount of nicotine found in tobacco is decidedly less than commonly recorded. Thus instead of the 6 to 8 per cent. of nicotine as given by analytical authorities, it has been found that the tobaccos consumed by the public contain seldom more than 3 per cent. of nicotine, the average being about 2 per cent. or under. The highest amount is found in Perique, which as a rule is not smoked alone, but in mixtures containing various amounts of it. Cigars contain a smaller proportion of nicotine than pipe mixtures or even some cigarettes. There is very little difference in the amount of nicotine in American, Turkish, and Egyptian cigarettes. French tobacco contains a good deal more nicotine than any of these. Pipe mixtures contain more nicotine than cigarettes. An Havana cigar contains the least amount of nicotine (0.64 per cent.)

Of more importance than the amount of nicotine contained in the tobacco is the amount contained in the smoke drawn into the mouth. This varies widely not only in the different methods of smoking, but also with the different varieties of tobacco used. Thus one Virginia cigarette containing a nicotine value of 1.40 per cent., gave up only 0.12 per cent. to the smoke, while another Virginia cigarette containing 1.60 per cent. of nicotine yielded only 0.06 per cent. of the latter to the smoke. The same tobaccos, however, when smoked in the pipe, yielded to the smoke respectively 53 and 37.5 per cent. of the nicotine. The reason for these differences is the fact that the combustion of tobacco in the cigarette is more complete than the combustion in the pipe. There is free access of air to the burning cigarette end, while in the pipe the tobacco is in a kind of retort, and the hot gases formed carry nicotine into the smoke. Although combustion in the cigarette is more complete than in the pipe or cigar, nevertheless cigarette smoke contains injurious substances other than nicotine, among which are mentioned aldehydes, including acrylaldehyde or acrolein, a class of bodies noted for their intense irritating effects. Although pipe mixtures yield a large amount of nicotine to the smoke, they also yield a very large proportion of basic substances, including ammonia, and it is surmised that these bases prevent the formation of the irritating compounds often found in cigarette smoke.

On the whole it appears from these investigations that the cigar represents the least injurious form in which tobacco may be smoked, a fact which coincides exactly with popular experience. The choice of a cigar is, however, not only a matter of taste and extent of purse, but also of scientific discrimination. While a British cigar containing 1.24 per cent. of nicotine yields 83 per cent. of this to the smoke, the Havana cigar containing 0.64 per cent. of nicotine, liberates only 31 per cent. of this. Thus science acknowledges the supremacy of the Havana cigar in the domain of tobacco.

SODIUM NUCLEATE IN THE TREATMENT OF SCARLET FEVER.

Various nuclein preparations have been used in medicine and surgery as therapeutic and prophylactic remedies, ever since Mikulicz showed the powerful action of nucleic acid in calling forth a leucocytosis. It has been shown experimentally that nucleic acid partly protects animals from peritoneal infections, that it seems to have an abortive effect on such infections as erysipelas, and that in general it is of effect in indolent infections where very little reaction is apparent in the infected organism. Writing in *Russkii Vrach* for March 3, 1912, M. G. Molyakoff tells of his experiences with sodium nucleate in the treatment of scarlet fever, his observations being of sufficient interest to deserve a wider circle of readers than the Russian journal affords.

Molyakoff treated altogether 90 cases of scarlet fever, 7 of which reached the hospital on the second day of the disease. The most favorable effect of sodium nucleate appeared to have taken place among children of this group. The injection led to a rise in leucocytosis and the disease, or rather the toxemia as marked by fever, seemed to have been quickly aborted, the high temperature dropping to normal in from one to three days. None of these children died. To the second group belonged children that reached the hospital on the third to the sixth day of the disease. No abortive effect of nuclein was noted in this group of cases, yet it seemed to Molyakoff as if the mortality in the 71 members of the group was lower than is usually the case with scarlet fever patients in the Russian provinces. Three children of this group died, two from phlegmonous inflammation of the neck, one from cardiac failure. The third group of patients comprised those who reached the hospital late in the disease; there were few of them, and no effect, favorable or un-

favorable, was noted from the injections of sodium nucleate.

Molyakoff has also tried similar injections in a few cases of typhoid fever and of acute articular rheumatism. No effect was noted in the first condition, while in rheumatism the injections seemed to have exercised some favorable influence and especially had an analgesic effect on the joint pains. Molyakoff used a solution of sodium nucleate in 30 to 50 c.c. of distilled water using 0.1 gram for each year of the child's age. The solution was sterilized by boiling for five minutes. No untoward effects, beyond occasional headches, were noted.

The Titanic Disaster and Its Medical Heroes.

Then rose from sea to sky the wild farewell—
Then shriek'd the timid and stood still the brave—
Then some leap'd overboard with dreadfull yell,
As eager to anticipate the grave.

In almost every pitiful detail the lines written by Byron nearly one hundred years ago are descriptive of the scenes associated with the sinking of the *Titanic*. As one contemplates the harrowing fate of the fifteen hundred martyrs of the sea, there grows the feeling of admiration for those qualities of chivalry which leaped like a beacon out of the gloom and terror of the early morning hours of April 15. The mastery of civilization over the primitive instinct of self-preservation was never exemplified by greater heroism and devotion. Medical men should feel a sense of pride that the time-honored traditions of their guild were not violated in those trying hours. Dr. William F. N. O'Loughlin, the chief surgeon of the ship, was active to the last in the service of others. Buckling life belts on to more than a score of women and carrying many of them to the life boats, calming the frightened passengers, and in every other way striving to create order, the gallant surgeon finally awaited death with resignation. The sea claimed one who had served her faithfully for forty years, one whose ministrations to poor and rich alike had endeared him to thousands of travelers. Several other physicians among the passengers, together with the surgeons of the ship, went down, as thousands of others of our calling have met death in laboratory or lazaretto, or courted it fearlessly on the battlefields of war or of pestilence. All honor to those who shared the watery grave with their precious charges.

The Senile Heart.

The death by heart-failure of General Frederick D. Grant emphasizes the repeated warnings of the medical profession that we should treat a senile heart with respect. As far as we know there is not the slightest disagreement on this one point—every human heart over 50 and perhaps over 45, cannot stand much internal pressure without being ruined or at least damaged. A very slight man may go through severe muscular exertion with but little damage, but a heavy man, like the General, places on the heart and arteries a hydrostatic pressure beyond the safety point and it never recovers. When the system is placed under an extra strain by disease, the heart cannot stand it. The annual riding endurance tests are beyond human endurance. The pitiful feature of this deplorable death is the fact that General Grant in his last annual report had called attention to the opinion of life insurance examiners that army officers were becoming poor risks on account of the increasing strains of their profession. There is a suspicion that he felt it himself and was fully aware that a disease which would not ordinarily be fatal for many years, would kill him promptly. The increasing body of lay opinion against excessive exertion should now have some weight in preventing unnecessary strains in the future. The Surgeon General of the navy has shown that "trained" athletes do not last as well in the navy as the non-athletic. The statistics of Anderson of Yale do show that "Y" men in the last fifty years have had less mortality than the "weaklings" who could not compete, but the difference should be greater, for such perfect specimens ought to have far less mortality. It is safe to predict more deaths like General Grant's, unless we treat the heart of a man over 45 with more gentleness.

Syphilis and Paresis.

The most practicable method of studying this relationship has always been to trace the paresis back to syphilitic infection, and in certain cases this has been possible up to a negligible residue, so that most neurologists believe fully in the dictum "no syphilis, no paresis." The number of syphilitics doomed to become paralytic dements, and the influence of collateral factors have been much harder to arrive at. At a recent session of the Royal Imperial Society of Physicians in Vienna (*Berliner klinische Wochenschrift,* Feb. 19) Mattauschek and Pilcz make public the results of a collosal research which was conducted as follows: The army officers, 4,134 in number, who were known to have become syphilitic during the period 1880-1900 were all followed up to ascertain the proportion which developed paresis. This was found to be 4.67 per cent. It was also ascertained that by far the greater number of these had either suffered very little from the infection, or had been treated insufficiently. The two factors are naturally associated, for the mild, nonrelapsing cases are the very ones which naturally go untreated. But the most thorough antiluetic treatment is not always able to ward off paresis. More than this the statistics do not teach, although the paretic syphilitics were controlled by study of the nonparetic material. It appears that under protracted intermittent treatment the chance of paresis developing is somewhat less than under a single term of early treatment. Any sort of febrile infectious disease in the first year of syphilis seems to predispose the patient to paresis.

Can Normal Tissue Cells Be Cultivated in Vitro?

With that commendable conservatism which illustrates how little responsible scientists are influenced *à priori* by new discoveries alleged to have been made by their colleagues, leading pathologists in Germany who have repeated the original experiments have expressed themselves somewhat skeptically as to the nature of the supposed prolification of tissue cells *in vitro*. Some of the cell elements undoubtedly appear to multiply, but the phenomenon, they say, is susceptible of a very different explanation. The entire subject was vigorously debated before the Medical Section of the Schlesischen Gesellschaft für vaterlandische Kultur, Breslau, last December (*Berliner klinische Wochenschrift,* January 20). Among those who had repeated the English and American experiments were Pfeiffer and

Praussnitz while others present had had opportunity to study the preparations. Praussnitz explains the phenomenon as follows: The tissue placed in the culture medium undergoes autolytic changes which result in an aseptic necrobrosis. The connective tissue cells either migrate or are washed out into the nutrient plasma. That they may proliferate is not impossible, but strict proofs have not thus far been supplied. The speaker had experimented only with adult tissues, the reason being that the novelty of the discovery obtained only for fully developed structures. That embryonal tissue can continue to grow *in vitro* is not apparently in dispute, but it has commonly been denied that adult tissues possess the same property. That the connective-tissue cells of the latter do not undergo true proliferation is said to be evident from a comparison with the intracellular finds seen in actual growth. Carrel admits that mitoses do not occur regularly. The entire subject is of course one for earnest and patient investigation.

News of the Week.

Polyclinic Hospital.—The new quarters of the New York Polyclinic Hospital at 347 West Fiftieth Street, New York, were open for inspection last week. It is expected that they will be ready for the reception of patients about May 1. The building consists of ten stories, two basements, and a roof garden, the tenth floor being devoted to the kitchens. On the ninth floor is the operating room, dedicated to Dr. William A. Pryor. The roof garden commands a wide view of the city and of the Hudson River, and should be cool in summer; in winter it will be inclosed in glass and heated.

Police Surgeons to Parade.—Commissioner of Police Waldo of New York has ordered that this year the police surgeons of the city must join in the annual department parade, and must, furthermore, appear on horseback. Heretofore, it has been a matter of individual decision whether a surgeon paraded or not, and but few have, as a rule, cared to take advantage of the occasion to make a public display of their horsemanship.

Sterilization of Criminals.—Governor Dix of New York recently signed the bill passed by the Legislature providing for the sterilization of certain classes of male criminals and defectives confined in State institutions. The new law, which is in the form of an addition to the public health law, creates a board, to be known as the Board of Examiners of Feeble Minded, Criminals, and Other Defectives, to have supervision over the matter, the board to be made up of one surgeon, one neurologist, and one medical practitioner, each with ten years' experience. If after examination this board decides that an inmate of the class affected by the law would transmit to his offspring a tendency to crime, insanity, or feeble-mindedness, or that his own mental condition would be improved thereby, it is to appoint one of its members to perform the necessary operation. The law applies to those who have been convicted of rape or of such a succession of offences as the board may consider to afford sufficient evidence of confirmed criminal tendencies. The operations of the law are safeguarded by the provisions for a judicial review of the findings of the board before any operation is performed, and no order of the board can become effective until it has been on file for five days. Careful records are to be kept of the effect of the law's application. New York is the sixth State to adopt such a law, New Jersey and Illinois being among those in which such action has already been taken.

School Reorganized.—The University of California Medical School was recently reorganized with Dr. Herbert G. Moffitt as Dean. Dr. Wallace I. Terry heads the department of surgery, and Dr. W. W. Kerr that of medicine. The new plans include the concentration of the work of the school in San Francisco in a hospital to be built from funds furnished by friends of the school.

To Transfer Lepers.—The Government, it is said, proposes to transfer the leper colony of the Island of Guam to the Philippines, where the lepers are interned on Culion Island. Congressional action will probably be necessary as the appropriation made for the support of the lepers at Guam cannot be used for transferring them to or for maintaining them in the Philippines.

Infantile Paralysis.—The reports of the United States Public Health and Marine Hospital Service shows that whereas 5,861 cases of infantile paralysis with 950 deaths were reported during 1910, there were in 1911 only 1,033 cases with 440 deaths. During the past two years the disease was prevalent in all sections of the country, including Alaska.

Health Department Moves.—The offices of the Department of Health of the City of New York have been removed from the building at the corner of Sixth Avenue and Fifty-fifth Street, where they have been housed for some time, to the new headquarters building on the corner of Walker and Centre Streets. It is expected that the moving will be completed and the old building abandoned by the first of May.

Charitable Gifts.—By the will of the late Moses Weinmann of New York the sum of $5,000 each is left to the Mt. Sinai Hospital, the Beth Israel Hospital, the German Hospital Dispensary, the Montefiore Home, the Presbyterian Hospital, and St. Vincent's Hospital. By the will of the late Andre F. Bornot, of Philadelphia, the residue of his estate is bequeathed to St. Joseph's Hospital, St. Vincent's Home for Children, and the Church Home for Children. By the will of the late Harriet Evans, of Philadelphia, the sum of $5,000 is bequeathed to the Presbyterian Home for Aged Couples and Aged Men at Bala, $5,000 to the Presbyterian Orphanage, and $5,000 to the Philadelphia Home for Incurables.

Dr. John F. Anderson, director of the Hygienic Laboratory, U. S. Public Health and Marine Hospital Service, will deliver the Cutter Lecture on Preventive Medicine at the Harvard University Medical School on May 9 at 5 o'clock. The subject will be "Some Recent Advances in Our Knowledge of Certain Infectious Diseases." This is the second of a series of lectures to be given annually under the terms of a bequest from John Clarence Cutter. The lectures are free to the medical profession.

Dr. S. A. Knopf will deliver the oration on medicine before the Illinois State Medical Society on May 23, the title of the address being "Some Modern Medico-Sociological Conceptions of the Alcohol, Venereal Diseases, and Tuberculosis Problems."

Health Statistics for March.—The death rate in New York City for the month of March, 1912, was 16.01, a decrease of 1.59 as compared with the same month of 1911, when the rate was 17.60. The number of deaths was 7,030, a decrease of 415. The mortality from the communicable diseases was con-

siderably increased with the exception of measles and pulmonary tuberculosis, in which there were increases of 17 and 67 respectively. The decrease was especially marked in influenza, bronchitis, and pneumonia, the deaths due to these diseases totaling 207 less than last year. The mortality from cancer showed the increase which has been marked all through the last decade. The number of births reported was 11,463, a decrease of 180 from the total in March, 1911, while on the other hand the number of marriages reported increased from 3,412 to 3,436.

Death of Centenarian.—Mrs. Ida Oshinsky of Hancock, Mich., reported to be the oldest person in the State, died on April 13 at the age of 108 years.

The International Conference on Tuberculosis began its sessions in Rome on April 11, as a preliminary to the International Congress. A large number of delegates from America attended the discussions.

Bad Butter Seized.—By the order of the United States Government, Marshall Henkel recently seized in New York 30,000 pounds of decomposed butter which was in the possession of the West Shore Railroad, having been shipped from Chicago. The inspectors reported that the butter bore a close resemblance to Roquefort cheese.

New Hospital Building.—Plans have been filed for the erection of an eight-story building for the Beth David Hospital Association. The hospital will stand on the northwest corner of Lexington Avenue and One Hundred and Thirteenth Street, and will have a frontage of 60.11 feet on the avenue and 73.10 feet on the street. The facade will be of brick and terra cotta.

Willed His Brain to Science.—It has become known that the brain of the late Vladimir Koch, assistant professor of pharmacology in the University of Chicago, was willed to the Wistar Institute, of Philadelphia.

Philadelphia Medical Club.—A reception was given by the club on the evening of April 19 in honor of Mr. Charles C. Harrison, formerly Provost of the University of Pennsylvania, Mr. John H. McFadden, President of the Art Club; Mr. William Potter, President of the Board of Trustees of Jefferson Medical College, and Mr. Edward T. Stotesbury.

National Conference on Pellagra.—In response to invitations from the State Medical Association and the State Board of Health of South Carolina, the National Association for the Study of Pellagra will hold its next triennial meeting in Columbia, S. C., October 3 and 4, 1912, the week following the Washington meeting of the Fifteenth International Congress on Hygiene and Demography. An invitation is extended to all persons interested in pellagra to participate in this meeting. The cooperation of officers of the Government Medical Service, State Boards of Health, and State Hospitals for the Insane is especially solicited. Persons wishing to present papers will address the special committee, consisting of Drs. J. W. Babcock, J. J. Watson, and J. H. Hayne, Columbia, S. C.

Massachusetts State Medical Society.—At the annual meeting held on April 11, in Boston, the following officers were elected: *President*, Dr. George R. Southwick, Boston; *Vice-Presidents*, Dr. J. Herbert Moore, Brookline, and Dr. John H. Bennett, Pawtucket; *Secretary*, Dr. Edward S. Calderwood.

Fairfield County (Conn.) Medical Association.—The annual meeting was held in Bridgeport on April 9, when the following officers were elected for the ensuing year: *President*, Dr. James Douglas Gold, Bridgeport; *Secretary*, Dr. Frank W. Stevens, Bridgeport; *Treasurer*, Dr. Philip W. Bill.

Monongalia County (W. Va.) Medical Society.—At the annual meeting held in Morgantown on April 9, the following officers were elected: *President*, Dr. R. Coale Price; *Vice-President*, Dr. Clyde Watson; *Secretary*, Dr. E. R. Taylor; *Treasurer*, Dr. James A. Cox.

Rock Island County (Ill.) Medical Society.—The annual meeing was held on April 9, officers being elected for the ensuing year as follows: *President*, Dr. E. Sargent, Moline; *Vice-President*, Dr. W. D. Snively, Rock Island, and Dr. F. E. Clarke, Watertown; *Secretary*, Dr. W. D. Chapman, Silvis; *Treasurer*, Dr. A. T. Leipold, Moline.

The Georgia State Association of Health Officers held its annual meeting in Augusta April 16, and elected the following officers: *President*, Dr. E. E. Murphy of Augusta; *Secretary-Treasurer*, Mr. A. V. Wood of Brunswick.

The South Carolina State Medical Association met at Columbia, S. C., and elected the following officers: *President*, Dr. Chares M. Reese of Charleston; *Secretary*, Dr. E. A. Hines of Seneca. Rock Hill was selected as the next meeting place.

The Medical Association of Georgia has elected the following officers: *President*, Dr. W. W. Pilcher of Warrenton; *First Vice-President*, Dr. J. W. Palmer of Ailey; *Second Vice-President*, Dr. T. H. Hall of Macon; *Secretary and Treasurer*, Dr. W. C. Lyle of Augusta. Next place of meeting, Savannah, beginning the third Wednesday in April.

Northwest Texas Medical Association.—At the annual meeting held in Cisco on April 9, the following officers were elected: *President*, Dr. Allen Ivy, Waterford; *Vice-President*, Dr. B. F. Jones, Cisco; *Secretary*, Dr. A. D. Patillo, Petrolia.

Middlesex County (Conn.) Medical Society.—The annual meeting was held on April 11, when officers were elected as follows: *President*, Dr. F. B. Bradeen, Essex; *Clerk*, Dr. A. B. Coleburn, Middletown; *Censors*, Drs. M. C. Hazen, J. H. Kingman, and John E. Loveland.

Brockton (Mass.) Medical Society.—The following officers were elected at the annual meeting on April 11: *President*, Dr. R. A. Elliott, Avon; *Vice-President*, Dr. Harry R. Cloudman; *Secretary*, Dr. H. A. Chase; *Treasurer*, Dr. Joseph E. Brady.

New London County (Conn.) Medical Society.—The national reciprocity bill now pending in Congress whereby a physician holding a license to practise in one State is allowed the right to practise in all others as well, was endorsed at the meeting of this sociey held on April 4. The following officers were elected at the meeting: *President*, Dr. E. P. Brewer of Norwich; *Vice-President*, Dr. W. H. Gray of Mystic; *Clerk*, Dr. E. Oliver Winship of New London.

Iberville Parish (La.) Medical Society.—At the annual meeting in White Castle on April 4 the following officers were elected: *President*, Dr. A. A. Landry of Vaincourtville; *Vice-President*, Dr. E. O. Graham of New Orleans; *Secretary*, Dr. Rome D. Martinez.

Denison (Texas) Medical Society.—The election of officers at the annual meeting on April 4 resulted as follows: *President*, Dr. A. V. Rutledge; *Vice-President*, Dr. J. C. Carter; *Secretary-Treasurer*, Dr. J. A. Rutledge.

Tri-County (Ga.) Medical Society.—The annual meeting of this society, which embraces the counties of Early, Calhoun, and Miller, was held in Blakely on April 3 and the following officers were elected: *President*, Dr. P. H. Fitzgerald of Blakely; *Vice-President*, Dr. C. K. Sharp of Arlington; *Secretary-Treasurer*, Dr. J. G. Standifer of Blakely.

Obituary Notes.—Dr. Paul C. Freer, director of the Bureau of Science in the Philippine Islands, and dean of the College of Medicine in the University of the Philippines, died in Manila on April 17, aged 50 years. Dr. Freer was born in Chicago, and received his medical degree from Rush Medical College in that city in 1883. In 1887 he received the degree of Ph.D. from the University of Munich, and in succeeding years was assistant chemist at Tufts College and instructor and later professor of chemistry at the University of Michigan. In 1901 he was appointed superintendent of the Government laboratories in Manila and a member of the Philippine Islands Board of Health; and in 1905 became director of the Bureau of Science. Dr. Freer was editor of the *Philippine Journal of Science* and a member of many chemical and medical societies.

Dr. Samuel Oakley Van der Poel died at his home in this city on April 22. He was born in Albany in 1853, was graduated from Rutgers College in 1873, and from the College of Physicians and Surgeons, New York, in 1876. After serving for a year and a half as an interne in Bellevue Hospital he pursued his postgraduate studies in Vienna. On returning to this country he went to Albany to practise and was appointed adjunct professor of the theory and practice of medicine in the Albany Medical College. In 1885 he came to New York City, where he resided continuously thereafter. He was formerly visiting physician to the City Hospital and at Randall's Island, assistant surgeon to the Manhattan Eye and Ear Infirmary, and assistant in the throat department of the Vanderbilt Clinic. For fourteen years he was medical director of the New York Life Insurance Company. He was a member of the medical societies of the county and State of New York, of the New York Academy of Medicine, of the American Laryngological Society, and of the Society of Alumni of Bellevue Hospital. Dr. Van der Poel came from a medical family, both his grandfather, his father, and his uncle having been physicians, and his brother also is a physician of this city.

Dr. Francis W. Bowron of Brooklyn, N. Y., a graduate of the New York University Medical College in 1870, and a member of the New York State and Kings County Medical Societies, died at his home after a long illness on April 11, aged 65 years.

Dr. Horace Wardner Eggleston of Binghamton, N. Y., a graduate of the University of Vermont College of Medicine, Burlington, in 1895, and formerly first assistant in the Binghamton State Hospital, died at his home on April 11.

Dr. Russell Broughton of Rockford, Ill., a graduate of the Rush Medical College, Chicago, a veteran of the Civil War, and a member of the American Medical Association and of the Illinois State and Winnebago County Medical Societies, died at his home on April 4, aged 69 years.

Dr. James David Thorburn of Toronto, Ontario, a graduate of the Toronto University Medical Faculty in 1887, and a member of the College of Physicians and Surgeons, died after an operation for appendicitis on March 19.

Dr. Ira Adelbert Hix of Binghamton, N. Y., a graduate of the New York University Medical College in 1883, and a member of the New York State and Broome County Medical Societies, died at his home of typhoid fever on April 12, aged 53 years.

Dr. Philippe Ricord of Newark, N. J., a graduate of the College of Physicians and Surgeons, New York, in 1868, and a member of the New Jersey State and Essex County Medical Societies, died on April 10 of pneumonia, aged 69 years.

Dr. George L. Reagan of Berwick, Pa., a graduate of the University of Vermont College of Medicine, Burlington, in 1865, formerly president of the Berwick Borough Council, and a member of the Pennsylvania State and Columbia County Medical Societies, died at his home on April 8, aged 75 years.

Dr. H. Preston Gilstrap of Kansas City, Mo., a graduate of the Washington University of St. Louis, Department of Medicine, in 1896, died suddenly on April 4, aged 45 years.

Dr. Truman M. Griffith of Pittsfield, Me., a graduate of the New York University Medical College in 1883 and a member of the Maine State and Somerset County Medical Societies, died at his home after a long illness on April 8, aged 59 years.

Dr. William C. Maloy of Atlanta, Ga., a graduate of the University of Georgia Department of Medicine in 1890, and a member of the Georgia State and Dodge County Medical Societies, died after a short illness of appendicitis on April 3, aged 56 years.

Dr. Walter A. Russell of Everett, Mass., a graduate of the Bellevue Hospital Medical College in 1898, and a member of the American Medical Association and the Rhode Island State Medical Society, died at his home suddenly on April 5, aged 39 years.

Dr. Thomas Virgil Hubbard of Atlanta, Ga., a graduate of the Atlanta Medical College in 1892, and a member of the Georgia State and Fulton County Medical Societies, died suddenly at his home on April 4, aged 43 years.

Dr. James D. Marsh died of apoplexy at North Bethlehem, Pa., on April 11 at the age of 60 years. He was graduated from Jefferson Medical College in the class of 1882.

Dr. Albert Henry Allen, a graduate of the College of Physicians and Surgeons, New York, in the class of 1904, and a member of the New York State and Franklin County Medical Societies, the American Medical Association, and the National Association for the Prevention of Tuberculosis, died in Saranac Lake, New York, on April 12, of tuberculosis, after a long illness, aged 37 years.

Dr. Victor Seymour Pier of Brooklyn, New York, a graduate of the College of Physicians and Surgeons, New York, in 1901, a member of the New York State and Kings County Medical Societies, and associate in gastroenterology in the Brooklyn Hospital, and physician to the Brooklyn Hospital Dispensary, died at his home on April 17, aged 36 years.

Dr. Henry A. France of Far Rockaway, New York, a graduate of the Albany Medical College in 1864, a veteran of the Civil War, and a former postmaster of Far Rockaway, died at his home on April 15, aged 70 years.

Dr. Warren B. Maxwell of Grafton, Mass., a graduate of the Dartmouth Medical School, Hanover, N. H., in 1876, died at his home on April 11, of pneumonia, aged 64 years.

Dr. Henry C. Miner of Topeka, Kan., a graduate of the Northwestern University Medical College, Chicago, in 1875, and a member of the Kansas State and Shawnee County Medical Societies, died at his home on April 4, aged 70 years.

Dr. Henry Martin Blake of Monmouth, Me., a graduate of the Bellevue Hospital Medical College in 1868, and a member of the Maine State and Kennebec County Medical Societies, died at his home on April 7, aged 75 years.

Dr. Frank Lee Drummond Rust of Boston, Mass., a graduate of the Harvard University Medical School in 1897, ophthalmic surgeon to the Carney Hospital, and assistant professor of ophthalmology at Tufts College Medical School, and a member of the Massachusetts State and Suffolk County Medical Societies, died at his home of septicemia on April 10, aged 38 years.

Dr. Mark J. Lehman of New Orleans, La., a graduate of the Medical College of Alabama, Mobile, in 1873, and formerly a member of the United States Public Health and Marine Hospital Service, died at his home on April 7, aged 57 years.

Dr. John P. Soliss of Sapulpa, Okla., a graduate of the Hahnemann Medical College and Hospital of Chicago in 1895, and a member of the Oklahoma State and Illinois State Medical Societies, died at his home on April 7, aged 63 years.

Correspondence.

THE MODIFICATION OF COW'S MILK.

To the Editor of the Medical Record:

Sir:—Referring to the milk formula printed in your journal on March 23, 1912, Dr. L. Monk has expressed his dissatisfaction with the excessive amount of proteins and the small amount of sugar. I am sorry that Dr. Monk had not consulted some one as to the exact percentage of the constituents in cow's milk. The average of a large number of analyses on milk made in this country shows* the percentage of proteins to be 3.30. Dr. L. Monk's objection is that the modified milk according to my formula will be 0.5 per cent. richer in proteins than it should be. But he is mistaken. The actual percentage of proteins in cow's milk is 3.30. The 7½ oz. of whole milk + 2½ oz. top milk employed in my formula contain therefore not 40 per cent. of proteins but 33 per cent.

The excess of proteins in the 20 oz. mixture is therefore not 10 per cent., as Dr. Monk thinks, but 3 per cent. This minimal deviation from the exact 1.5 per cent. of proteins intended for a child 6 months old is quite allowable when we bear in mind the fact that when we employ other formulas the deviation from the exact 1.5 per cent. of proteins is greater. In regard to the amount of sugar missing I thank Dr. Monk for calling my attention to the fact that I made a mistake in writing 120 instead of 140, which would give the child one oz. of sugar instead of 6.5 drams.

Dr. L. Monk is also mistaken in thinking that the formula cannot be used in every case. By careful calculations it can easily be utilized by the mother as well as by the physician. I doubt if there is a mother that would not understand this. In regard to the extra expense I do not see where that comes in. Two pints of milk cost exactly as much as one quart of milk. I trust that this will be understood and that with the method of calculating given in the original formula every intelligent physician will be able to use it with satisfaction.

M. A. Helfgott.

OUR LONDON LETTER.

(From Our Regular Correspondent.)

ELECTROCARDIOGRAMS—CANCER OF THE COLON—CARBOLIC ACID AND QUININE IN PLAGUE—A PROFITABLE SEWAGE DISPOSAL SCHEME—ROYAL COLLEGE OF PHYSICIANS—OBITUARY.

London, April 4, 1912.

The debate on Circulatory Disorders at the Chelsea Clinical Society extended over two evenings. Sir Clifford Allbutt's opening address, of which I sent you an account last week, gave rise to some important remarks at the first, showing that the experience of some of our ablest physicians as to cardiac failure amounted to little. One talked of toxic conundrums and the need of research on the poisoning of snakes and of uremia and diabetes. Others spoke not only of the little known, but of the unknowable conditions which resulted in such contradictory experiences that a strict examination for life insurance in which nothing was detected might soon be followed by sudden death while another patient with gross changes lingered on and eventually died of senile decay with no sign of heart failure. But the interest of the second evening quite eclipsed that of the first for Professor Einthoven of Leyden read a paper on the Human Cardiogram and was followed by Prof. A. D. Waller from the physiological aspect, and he by Dr. Thomas Lewis, to whom more than any one, at any rate in this country, is due the extension of Einthoven's method to clinical investigation. The annual dinner of the Chelsea Clinical Society was also held on the 20th of March and naturally Prof. Einthoven was the guest of the evening, none of the speakers omitting to pay him compliments to which in due course he gracefully replied that his electrocardiogram had demonstrated the goodheartedness of English doctors. In addition to all this we honored the distinguished visitor at the R. S. M., where a special meeting was held in the Clinical Section for him to give a demonstration which was illustrated by lantern slides. You will readily understand that a full exposition of his views as stated at the two societies would fill ten or a dozen pages of the Record and that I can therefore only mention a few points without referring them to either meeting and so with the comments made by others.

The professor pointed out that his method shows the time relation between the action of the ventricles and auricles and enables the difference in time between them to be accurately and easily measured. Further, it gives a new insight into several diseases, among which must be mentioned auricular fibrillation. It shows, too, that the pulse is an important guide to cardiac action. Differences in magnitude of pulse do not necessarily correspond with differences of strength of cardiac contractions. A forcible ventricular contraction may produce only a feeble or even imperceptible pulse, if at the moment the left ventricle is not sufficiently full, which will be the case if the contraction of the auricles has not just preceded it or is insufficient itself. The irregularity of the pulse in auricular fibrillation is due to auricular, not to ventricular, irregularity. *Pulsus alternans* in which every second beat is small and feeble is probably due to inequality in the

strength of ventricular contractions. Tachycardia may be shown to exist by the electrocardiogram when the pulse is not rapid. We may judge the state of the heart muscle more accurately by the cardiogram than by pressure curves from the pulse. "Electrocardiography," said Prof. Einthoven, "is still a young plant. We may reasonably expect that it will continue to bear good fruit."

Dr. T. Lewis spoke of it as "a growing science," the value of which had received universal recognition—the instruments being installed wherever pathology and clinical medicine were efficiently studied. We were indebted to it for our knowledge of the site of the heart beat. It had shown us that the crises of paroxysmal tachycardia are not simple disturbances of innervation. It could detect not only functional disturbances of the main auriculoventricular bundle but also defects in its chief branches—a discovery of fundamental import in the study of heart diseases. Without an electrocardiographic examination the heart had not been completely examined.

Dr. Dally gave some account of a case illustrating the common experience that when heart-block has become complete the patient suffers less than while conduction is only partially interfered with. A series of electrocardiograms showed the auricular beats occurring at regular intervals but quite independently of the ventricular waves. This was only one example of the value of the method and he quoted from a personal letter he had lately received from Professor Lewellys Barker of Johns Hopkins University the following words: "It seems to me that sphygmography and phlebography have now in practical work little more than historical interest provided arrangements are made for electrocardiography."

Cancer of the colon is often associated with a second growth above or below—or with polypi. Mr. Cuthbert Wallace related in the Surgical Section a series of such cases and suggested these questions for consideration: Whether polypi below a malignant growth were produced by implantation of cells from the tumor and carried down with the feces; whether those above the growth were caused by regurgitation of feces carrying such cells upward; whether when two cancers were present in the large intestine the upper was always primary and the lower due to cells carried down. Mr. Gordon Watson said he rather thought multiple polypi were generally precursors of carcinoma. He mentioned a case in which no polypi could be seen by the sigmoidoscope but at the post mortem three months later a number were found below the growth. Mr. Symonds said that in the majority he had met with no polypi below these carcinomata. He had seen a case in which a number of polypi disappeared spontaneously.

At the Oxford Medical Society on the 8th of March Mr. W. L. Seymour gave some account of his experience as a medical plague officer during the two outbreaks in Scinde (1897-8). Guided by a long experience of the value in septic and infective diseases of carbolic acid and quinine he gave these internally, at the same time soaking the glands continually with carbolic oil (1 in 30) on lint. He claimed that in the second outbreak he obtained by this treatment a percentage of 75 recoveries. He mentioned that Kitasato found the bacillus did not grow in cultures after an hour's exposure to a 1 per cent. solution of carbolic acid, adding that he had himself found that quinine intensified the effect of that agent. He had no doubt that the spread of plague was rather by place infection than by transmission from person to person.

Bradford is to be congratulated on the success, pecuniarily, of its experiment in dealing with sewage, which has extended over ten years. The idea of the engineer was the recovery of the grease contained, and he has accomplished it, purifying it to a sufficient extent to dispose of it commercially. The solid residue after extraction of the grease he dries and compresses into blocks, which form a good manure, and are eagerly bought by farmers. The corporation deserves credit for boldly carrying forward the scheme. The buildings and plant have cost £60,000, but last year a profit was made of £30,000, and when some further buildings are completed it is expected to reach £50,000 a year. Profitable sanitation in the commercial sense is something to boast of. During the coal strike some of Bradford's manufacturers discovered that the blocks so far used as a manure on the land could be utilized as fuel.

At the Royal College of Physicians on Monday the president, Sir T. Barlow, Bart., delivered his annual address, in which he referred to the work of the college during the year, and noticed the diseases of those fellows who had died during that period. A vote of thanks was carried by acclamation, to which the president responded and vacated the chair. He was then almost unanimously re-elected, and having received again the insignia of office, plighted his faith once more and thanked the fellows for the new honor that had been done him.

Rev. J. G. F. Hearn, M.D., T.C.D., late chief of Dublin University Mission at Chota Nagpur, India, has died suddenly at Bournemouth, aged forty-five. He graduated in arts at Trinity College, Dublin, in 1891, took M.B., and B.Ch. in 1893, and the M.D. in 1896.

News has arrived of the decease of J. F. Rymer, M.R.C.S., who went as a medical missionary to Canada in 1907, intending to penetrate within the Arctic Circle and labor among the poor Indians at the several stations. He died in January at Fort Resolution.

Dr. R. A. Prichard, J.P., died on March 11, aged sixty-nine, at Conway, North Wales, where he settled in 1868, having qualified L.R.C.P. Ed. and M.R.C.S. Eng., the previous year. He attained a great practice, and took intense interest in the affairs of the borough, and during his career served as mayor and constable of the Casle no less than six times. In 1909 he was presented with a testimonial by the county in the shape of a handsome motor car. He at one time served in the volunteers and retired as surgeon-colonel.

Chronic Ulcer or Chronic Indigestion, Its Successful Teratment by Surgical Measures. A Report of Twenty-Five Cases. C. L. Scudder.
Chorionepithelioma. S. Rushmore.
The Relation of Gonorrhea to Pelvic Disease. G. W. Kann.
The Palliative and Operative Treatment of Anal Fissure. T. C. Hill.
A Delicate Method for Obtaining Hemin Crystals from Minute Blood Stains. W. F. Whitney.

Chronic Gastric or Duodenal Ulcer.—C. L. Scudder states that cases of intractable recurring dyspepsia in adult life are probably often cases of chronic duodenal or gastric ulcer. Cases of chronic ulcer of either the stomach or duodenum which have remained unhealed, as indicated by a persistence of symptoms, after carefully con-

ducted and skilled medical treatment for a period of from two to three months or longer are at present best treated by surgical measures. The reasons for surgical treatment in such cases are: (1) Medical treatment has failed to cure the trouble. (2) The exact duration and extent of the ulcer is unknown. Hemorrhage may occur and death result. (3) The stomach and duodenum may be perforated by the ulcer. (4) Carcinoma may develop upon the ulcer. (5) Obstruction at the pylorus may occur. (6) If untreated surgically, a still longer period of chronic invalidism will exist. (7) Surgery has demonstrated that it is possible to cure a large proportion of these chronic ulcers.

Relation of Gonorrhea to Pelvic Disease.—G. W. Kann believes that statements which claim that the gonococcus infection in the woman is responsible for 60 per cent. or more of the operations for pelvic inflammation are decided exaggerations and should be modified in the interest of truth and proper teaching. The statement that 45 per cent. of the cases of sterility are due to gonorrhea is also discredited by the reports of Bumm and Erb. From the figures obtained from hospital reports it is evident that operations for tubal disease represent from 5 to about 16 per cent. of gynecological operations, and even at that, the tubal disease is not always gonorrheal.

Treatment of Anal Fissure.—T. C. Hill states that a recent simple fissure without any hypertrophy of the external sphincter will invariably yield readily to palliative treatment; if there is only a slight degree of hypertrophy, excision of the fissure is sufficient; if there is a moderate degree only, dilatation under a general anesthetic is probably the best treatment; but if there is much hypertrophy and spasm, incision is the only operation that can be safely relied on to give permanent relief. This method has found almost universal favor among American proctologists and is practiced exclusively at the special hospitals for rectal diseases, St. Mark's and Gordons, in London. As first practised it consisted of a single complete division of all the fibers of the external sphincter muscle through the base of the fissure. It is now considered better practice to divide the muscle just to the right or left of the posterior median line, without regard to the location of the ulcer. The object of the operation is to eliminate the spasmodic action of the sphincters and so give the fissure a chance to heal. The incision should be made at right angles to the direction of the muscle fibers and carried outward for at least an inch to secure good drainage. It is important that the whole of the external muscle should be divided, and equally important to remember that one should be very careful not to injure the internal sphincter, as its division is invariably followed by some loss of control, if not absolute incontinence. Incision can be performed under local anesthesia in the majority of cases.

Dorsal Root Section in Treatment of Spastic Paraplegia.—By L. P. Clark and A. S. Taylor. (See MEDICAL RECORD, Vol. 80, page 643.)

Value of Massage.—J. M. Taylor notes that in cases in which there is local congestion, by means of properly executed massage, the hypertension in the vessels can often be relaxed, bringing about prompt relief to pathological processes which, if unrelieved, would progress to protracted or deep-seated disorder. In acute coryza, distributed finger pressures on the second, third, and fourth dorsal vertebræ on either side will open up the nasal passage on the corresponding side. Febrile headaches, or congestion of the head or sense organs, are readily relieved by slow, distributed pressures on the posterior occipital nerves, and on the second, third, and fourth dorsal vertebræ. Colicky pains due to spasm of the pylorus can be promptly relieved by distributed pressures along the fourth, fifth, sixth, and seventh dorsal vertebræ. Acute fevers accompanied by phenomena of congestion—dry skin, vascular hypertension, and swollen veins and lymph vessels, are readily relieved by gentle pressures along the erector spinæ muscles and ligaments of the backbone, bringing about prompt diaphoresis and easement of sensory and other phenomena.

Diagnosis of Tumors of the Breast.—G. Barrie states that the diagnosis of tumors of the breast is made from the historical facts obtained from the patient; from the clinical examination; from the gross pathological picture; and from the microscopic study of the tissue. The clinical picture, presented by the history and examination, may be sufficient to give ample justification for making a diagnosis, and indeed in a majority of the cases one sees, it should be a correct one; according to Rodman, in seventy-five per cent. There is no doubt that with advanced knowledge regarding tumor growth, and the keener interest and fear of delay manifested by the laity in these cases, the large percentage in which a positive diagnosis can now be made, owing to the advanced state of the growth, from the clinical evidence alone will in future be greatly reduced. The earlier the tumor is seen, the more difficult it is to make a positive diagnosis from the clinical facts. If, owing to the early stage of the growth, or unusual features in the history and examination, the clinical picture does not clarify the situation, section of the tumor mass and its appearance in the gross should practically always do so. The occasion should be rare when one is dependent upon the microscope to make the diagnosis. The microscopic picture, given by the frozen section for immediate diagnosis, is sometimes confusing to any but the expert cellular pathologist, and, outside of institutions, such methods of making diagnoses are not feasible. The microscopic picture of tumor tissue given by the frozen section, or more carefully prepared slide, ratifies a diagnosis already made or suspected from the clinical and gross pathological picture. In tumors belonging to the benign group, the cellular structure of the mass, as seen by the microscope, is generally uniform, without a typical cellular change. In malignant growths, architectural irregularity, cellular change, degeneration, and invasion are observed.

Cancer of the Pancreas.—M. Packard in summing up the evidence in favor of the diagnosis of cancer of the body and tail of the pancreas, states that one must never lose sight of pain, with its characteristic distress and prostration. If a tumor mass is felt, its fixation, and its disappearance when the stomach and colon are distended, will distinguish it from new growths of the gastrointestinal canal. It is well to remember that cancer in any part of the body will cause an absence of hydrochloric acid secretion by the stomach. In pancreatic cancer, if jaundice is present, the gall-bladder as a rule will be distended, differing from the contracted bladder of biliary calculi. The subnormal temperature and the emaciation will also help in reaching a diagnosis. In the clinical examination of the urine, it is always well to examine a number of specimens. In all there is likely to be a marked oxaluria, in some a trace of sugar. The stools are bulky, containing undigested meat fibres, and sometimes free fat.

Microscopically, the nuclei of the muscle fibres are undisturbed, and chemically, there is little split fats and the casein remains undigested.

Leucoplakia Buccalis.—R. H. Ivy reports three cases of this condition and presents the following conclusions, which argue against the syphilitic nature of this disease. In the large proportion of cases the patches occur without signs of any syphilitic lesion past or present, elsewhere in the body, and without any history of syphilitic infection. In the author's cases the lesions failed to respond to any form of antisyphilitic treatment. In two of the cases the Wassermann reaction was negative.

Anaphylaxis.—L. Hektoen presents a comprehensive review of this subject. He believes it not unlikely that the fatal sudden collapse sometimes seen in typhoid fever and in the crisis in pneumonia are anaphylactic phenomena. The cutaneous manifestations of other diseases, such as smallpox, may be of the same nature. There is little doubt that the tuberculin and similar reactions are of anaphylactic nature, and sympathetic ophthalmia, eclampsia, hay fever, and asthma, and various idiosyncrasies, may also be of the same character. The old idea that the introduction of microbes and their products induced distinctively protective reactions seems to be against the facts of anaphylaxis, but the contradiction is only apparent. The difference is in the susceptibility of the normal and the sensitized animal, the action being so rapid in the latter that the toxic substances are set free in toxic quantities while in the normal animal the process is so slow that the symptoms are not produced. There is no contradiction between immunity and allergy which is a form of antibody reaction and an incident in the course of immunization.

Treatment of Sacculated Aneurysm.—H. A. Hare reports six cases of sacculated aortic aneurysm treated by wiring and electrolysis, in addition to the fourteen cases already reported by him. In every instance the growth was so large that death in the early future was imminent and in several cases the wall of the sac was so thin as to be blue or blackish in hue and bloody serum was oozing through the skin. In most of the cases death eventually took place, but in many if not all of the cases life was prolonged and relief or partial relief from the severe pain was obtained. Much depends on the condition of the aortic wall, and if the aneurysm is due solely to traumatism there is a chance for success. On the other hand, if the vessel wall is extensively or severely diseased the treatment is like trying to mend a rotten hose. In four cases a second operation was done on account of the artery giving away at another point, and in one case, a third, the patient finally succumbing to the rupture of a fourth weak spot. While it may be admitted that cases of direct prolongation of life are rare, it must be remembered that the condition is, except in the very rarest instances, inevitably fatal, and any other treatment would be ineffective. Moreover, the condition is often unrecognized until it has become desperate. The operation is the only one that offers material hope of prolonging life, this having been prolonged in one case at least five years. It is justified by the prompt relief of pain, which nearly always ensues and lasts unless the growth, extending in another direction, creates a new source of pain.

Surgery in Ascites.—E. A. Babler states that epiploexy is indicated as soon as the internist makes the diagnosis of ascites secondary to vascular sclerosis of the liver. The operation is contraindicated in Bright's disease in patients over 55 or 60 years of age or those in whom the excretion of urea is greatly reduced, and in organic disease of the heart or lungs. If there is marked jaundice, emaciation and hebetude all surgeons practically agree against operation. Epiplopexy is indicated in luetic and alcoholic cases. In carefully selected cases before general impairment of health has occurred the results should be satisfactory in 90 per cent.

Cervical Rib.—E. S. Evans states that when long enough to be clinically demonstrated a cervical rib appears as a rather hard tumor in the supraclavicular region at the root of the neck, usually on the left side. It may give rise to pain of the dull aching variety and frequently most marked over the ulnar distribution, and aggravated by the use of the arm and by moderate degrees of cold and relieved by raising up the arms. Hyperesthesia, similarly distributed but sometimes over the whole arm, may occur and is frequently associated with the other two symptoms mentioned. The muscles supplied by the ulner nerve are notably liable to atrophy. Respiratory disturbance due to the irritation of the phrenic nerve in its course along the scalenus anticus by a long cervical rib is believed to be a possibility, and dysphonia, cough, and even laryngeal paralysis, are occasionally noted from pressure or irritation of the inferior laryngeal fibers by the rib or the arterial dilatation it causes. Vascular phenomena depend in part on a constriction of the artery between the rib and the scalenus anticus and in part on vasomotor influences not clearly understood. Cyanosis or blanching may occur, but compression of the artery does not always account for it. The salient points in the diagnosis are: (1) the *x*-ray; (2) ischemia, with cramps in the hand, persistent or continuously intermittent; (3) pain in the arm, gradually increasing over a considerable period of time, aggravated by moderate cold and by use, and alleviated by elevation; (4) brachial neuritis, especially of ulnar distribution, with atrophy of the interossei and the thenar and hypothenar eminences; (5) a small, firm, pulsating tumor in the supraclavicular region with or without accompanying symptoms of pain, atrophy, etc., is, nine times in ten, a cervical rib. It is estimated that only about 10 per cent. of cases of cervical rib have any symptoms at all. It must be differentiated from (1) aneurysm of the carotid, subclavian or vertebral arteries; (2) brachial neuritis; (3) bursitis of the subcapsular or subdeltoid bursæ; and (4) occupation neuroses. The treatment is obviously surgical and the results usually satisfactory in the cases that have produced symptoms.

Congenital Malposition of the Gall-bladder. A. J. Walton.
Telegraphists' Cramp. An Extract from the Report of the Departmental Committee, General Post Office, on the Subject, with Additional Matter. H. T. Thompson and J. Sinclair.

Significance of Skin Eruptions.—H. G. Adamson discusses first the eruptions due to physical injuries to the skin. An interesting and remarkable circumstance is the difference in length of time that elapses between the exposure to different kinds of injury and the resulting reac-

tions. To a mechanical injury, for instance, the reaction may be almost immediate; to burns it is a little delayed; to freezing (as with carbon dioxide snow) still further delayed; after application of a strong light (as the Finsen light) it does not occur for several hours, and after exposure to *x*-rays not for some days. The more unusual the kind of injury the more delayed the reaction. A possible explanation of this fact is that the tissues of the body have acquired a hypersensitiveness to damage done to them by the more common forms of physical injury. Those eruptions which are due to microbic invasion, may be of very varied aspect. For example, there are the scaly patches and broken hairs produced by the ringworm fungus, the vesicular and pustular lesions resulting from other ringworm fungi, the scaly macules of pityriasis versicolor, the comedo and the papulo-pustule of acne vulgaris, the follicular pustule of staphylococcic invasion, the vesicle or blister rapidly drying into a crust of streptococcic infection, the different types of eruption, papular, nodular, warty and gummatous—the result of infection by the tubercle bacillus, *Treponema pallidum*, sporotrichium, blastomyces, actinomyces, etc.; and to these are added the erythematous patches of a macular syphilide, the rose-spots of typhoid fever, and probably other erythematous eruptions. Blood vessel dilatation occurs in all of the deep-seated reactions, which are to be regarded as efforts of defence against microbes and their toxins.

Therapeutics of Lecithin and Phytin.—W. Bain concludes from clinical experience that lecithin is a valuable drug in cases of anemia and debility, and is to be regarded as a metabolic stimulus, for one can hardly conceive that the small amount of extra nitrogen and phosphorus administered in doses of a few grains daily can act as a tissue-former in any substantial degree. Its beneficial effect upon the nervous system is to be regarded as secondary to improvement in general nutritive condition, and not because lecithin is a "brain food." Its most striking effect is seen in the blood, the red corpuscles, white corpuscles (especially the lymphocytes), and hemoglobin percentage all being increased. Although there is some evidence that phytin (inosite phosphoric acid ester), a phosphorized constituent in vegetable tissues, may be of some value in herbivora, the evidence in favor of its utilization in carnivora and in man is either negative or conflicting.

Angina Abdominis.—Sir Lauder Brunton and W. E. Williams report the case of a patient aged 68 years who suffered from severe pain which came on when he began to walk. In this respect the pain resembled that of angina pectoris, but it differed in its position as it was most severe in the umbilical region. It was at first confined to the umbilical region and was attributed to flatulence, but it gradually increased in severity and extent so that it spread all over the front and back of the chest and caused perspiration to break out over his body. As this pain resembled so closely that of angina pectoris, but occurred in the abdomen, Brunton believed that it might well be termed angina abdominis, and that treatment similar to that of angina pectoris might be useful. He accordingly prescribed trinitrine with the most satisfactory results as it cut short the abdominal pain in the same way as it would have cut short anginal pain in the chest.

Late Syphilitic Glossitis Treated by Salvarsan.—Sir Malcolm Morris reports a case of severe late syphilitic glossitis, in which the tongue was eroded and painful and its surface irregular and lobulated. It was so swollen that it could only be protruded with difficulty, and the teeth could not be seen. There were deep fissures and at the tip it was split completely through. Ulcers were present both on the tongue and on the lower lip. The Wassermann reaction was positive. On November 18, 1911, 0.6 gram of salvarsan was injected intravenously, the saline being made from water distilled twenty-four hours before use. There was very little general reaction on the day of the injection, but there was marked swelling of the lower lip. On the second day the patient felt very sick and uncomfortable, and his temperature was 102° Fahr., but it fell to normal in the evening and remained so. On the tenth day after the injection the tongue was less swollen and not so painful; by the twelfth day the ulcers had disappeared. During December the fissures began to heal, those at the base in the direction of the tip, the cleft at the tip in the direction of the base. By January 15, 1912, the fissures were entirely healed and the tongue had returned to its normal size. One of the conclusions drawn by the author from the history of the case is that tertiary syphilis is more amenable to salvarsan than secondary syphilis.

Salvarsan.—G. G. Stopford-Taylor and R. W. Mackenna record their results in the treatment of ninety-three cases of syphilis by means of this remedy during the past sixteen months. They conclude that salvarsan is efficacious at every stage of the disease in eradicating lesions that have resisted mercury and the iodides. The ideal treatment is an initial intravenous injection of salvarsan, followed by vigorous mercurial treatment, and if necessary by another injection of salvarsan.

Chronic Purpura.—F. H. Edgeworth states that whereas the acute form of purpura is well known and recognized, the chronic form of the disease has attracted less attention. In this form the lesions continue for months or relapse again and again. An important point in the diagnosis is the differentiation from hemophilia. Unlike purpura hemorrhagica this is neither congenital nor hereditary. In hemophilia the blood shows a considerable diminution in coagulability, but the clot once formed contracts; in chronic purpura hemorrhagica coagulation takes place normally, but the clot does not contract. Further, in hemophilia there is no considerable diminution in the number of blood platelets; in purpura hemorrhagica this is a marked feature. The author reports three cases of chronic purpura. In one of these three hemorrhagic crises occurred in the course of four years—in the first hematuria, in the second hematuria and rectal hemorrhage, in the third hematuria with gastric and rectal hemorrhage. These attacks were not isolated—hematuria of variable degree was almost constantly present in the intervening periods and followed the last attack. No hemorrhage took place in the skin, or from the nose, mouth, pulmonary tract, and menstruation was normal in amount. The coagulation time of the blood was normal. Turpentine controlled the violent outbursts of bleeding, and arsenic apparently brought about a cessation of all symptoms

The Application of Tuberculin.—C. Riviere states that since the reactivity of patients varies enormously according to their sensitiveness and how far this is covered by tolerance, it is well to begin with a dose so low that it is certain to be ineffective. The dose may then be very rapidly raised till some effect is noted. This must be looked for in a local reaction, or, failing this in some slight general effect, such as a flattening of the temperature, or a slight rise, or slight symptoms in the patient. Having reached this point, the doses must be raised more gradually, and for the gradation of dosage nothing is more suitable than a geometrical progression such as that supplied by Lawrason Brown. By this means risk of large reactions is reduced to a minimum, and yet, with skilful adjustment, the dose may be kept sufficiently near the reacting point to efficiently call forth an immunizing response, the main points of which are a slight focal hyperemia and the stimulation of antibody formation. It is unlikely that fever reactions will be altogether avoided.

Perez's Sign.—W. Ewart states that this sign consists essentially in the production of sounds audible over the upper thoracic surface on actively or passively moving the arms at the shoulder-joint, and particularly on raising or lowering them. Shoulder girdle conduction is also capable of picking up audible vibrations of extra-articular origin in the vicinity of, or at a distance from the joints, from muscles or membranes in contact with any of the links in that pleximetric chain. This is of practical importance, particularly as any incomplete examination might be misleading as to the localization of the cause either within the chest or at any part of its upper circumference.

The Genesis of the Dicrotic Pulse Wave.—D. W. Samways believes that the dicrotic wave is a ballistic or catapult wave, due to the longitudinal recoil of the first part of the aorta, after it has been longitudinally stretched by the contracting heart. When the ventricle contracts with sufficient force the aortic valves open, and the blood in the aorta and in the ventricle forms one continuous column under pressure. This rigid column occupying the aorta and ventricle presses its foot on the inferior wall of the heart near the apex, and is probably a chief factor in preventing the apex from moving upwards when the ventricle contracts. In fact, the arch of the aorta and the lower wall of the ventricle are mutually repelled by the pressure of the blood column lying between them and thrusting them apart. With a ramrod of blood pushing it down, the apex cannot come up during contraction, and the base has to be drawn down toward it during ventricular contraction, pulling with it the aorta, which consequently lengthens. The aorta is drawn like the finger of a glove over the blood at the base of the ventricle, the remainder of the ventricular blood being driven through the aortic orifice after it. As the aortic pressure rises and the outflow from the ventricle decreases, the aortic valves are pushed toward one another by the blood behind them in the aorta, and are finally closed. The pressure of the aortic column now falls on the valves, supported temporarily from behind, Mackenzie suggests, by the "hard, contracted, ventricular walls." Something else, however, now happens. The pressure in the aorta near the heart begins to fall, and the longitudinally stretched aortic walls soon begin to recoil to their normal length, just as the circularly stretched walls have begun to return to their normal diameter. And just as the circular recoil drives onward through the arteries the main pulse wave, so the longitudinal recoil, which follows closely on it, shoots on a second wave—the dicrotic or ballistic wave.

March 18 and 25 and April 1, 1912

Progress in Living Tissue Cultivation.—Carrel states that the life of animal tissue cultivated in vitro is too brief to permit of the study of many important points; so that the rate of progress in this field should depend largely on the degree of success attainable in prolonging the life of the culture. In the earlier experiments growth phenomena were not observed after two weeks. Life could be prolonged by transportation to new media but only for a short time. The author developed this principle by transplanting at an earlier period, retransplanting and washing out the culture on each occasion in Ringer's solution. In this manner not only was fresh pabulum constantly available but any possible inhibiting influence of heaped up katabolic products was eliminated. The whole procedure was roughly parallel to that in which intact tissues are concerned. In life, naturally, the circulating blood brings the nutriment and bears away the waste products. During the operation of these attempts at the rejuvenation of cultures it became apparent that the persistence of life was expressed in two phases, visible and latent. The culture could be made to pass from one phase to the other by alternation. Individual cells were made to live through as many as 18 different transplantations. It has been possible to keep connective tissue alive for two months. To obtain the best results small portions of tissue are taken from the embryo of a chick. These must not be crushed, for this produces death. The best culture medium is either plasma diluted with distilled water, or serum-agar. Recently the author has discovered the important fact that the tissue products are able to induce marked hemolysis in goat's blood when the culture has been made with the aid of the latter. Hence the tissues are able to cause the formation of hemolytic antigens.

Artificial Choledochus (Drainage Tube).—Wilms has now replaced the ductus choledochus communis on five occasions with sections of ordinary drainage tube. This resource is to be used only when suture, implantation, etc., cannot be practiced. The first patient had a cancer of the duct which made it necessary to extirpate the latter. A hard rubber tube was sutured at one end into the hepatic duct while the other was passed obliquely through the duodenal wall. There was no external biliary fistula, and the tube functioned well for the three remaining months of the patient's life. The success of the procedure led the author to resort to it in four cases of cholelithiasis in which the integrity of the duct was badly compromised. In one case the duct was extirpated in the fear of cancer and the rubber drain has now been worn a year without discomfort or untoward results. In the next case the drainage tube was expelled and a jejunostomy had to be done. In the next case the common duct could not be found in the midst of the cicatricial tissue. The drain was used here chiefly to shorten the time of intervention as the woman was cachectic. The first drain escaped into the duodenum. Another was inserted and worn for a time but was eventually vomited up. The patient made a complete recovery, an internal fistula evidently carrying the bile satisfactorily into the intestine. In the last operation, the common duct was left inside and the drain made to traverse it. Four months later it was expelled by the stomach. An anastomosis was then performed—hepaticus to stomach. The author has shown that these tubes are very well tolerated, and that their use greatly abridges the operation in cachectic subjects who upon regaining their health may, if advisable, submit to a radical plastic operation.

Periodically Changing Pupil (Athetosis Pupillarum).—Erlenmeyer describes a pupillary phenomenon which differs to some extent from all other recorded forms of changing pupil. In regard to shape this changes from round to oval or rather its naturally round outline constantly changes. During the change there is mydriasis. Nevertheless the condition is not excentric mydriasis, for

in the latter the pupil always changes back to its natural shape. To describe the entire cycle of changes in the two eyes requires several good-sized paragraphs. The attacks last for 16 to 20 seconds. One may or may not be followed by numerous others within a short time. There is then evidently a long period of quiescence. Owing to the periodic objective character of the phenomenon it was only due to chance that the author was able to study it. Nevertheless the attacks were accompanied by amaurosis, due apparently to the incessant change in shape and location of the pupil, and members of the patient's family had often witnessed the phenomenon. The latter was doubtless part of a general seizure of the nature of a vasomotor crisis with vertigo and pseudo angina pectoris. There were also many features suggestive of hysteria. There was a possibility of beginning arteriosclerosis of the aorta and coronaries. The patient was 48 years old and her heart was hypertrophied. A psychosis could be excluded, likewise alkaloidal poisoning. The author suggests the name "athetosis of the pupils."

Influence of the Blood Glands on the Psychic Functions.—Münzer begins a serial article on this subject, in which he states first that affections of the hematopoietic and metabolic glands are often associated with a series of psychic disturbances. There is, in fact, an intimate relationship between these glands and the central nervous system. Since we are almost in the dark as to the true nature of psychoses, this relationship should by all means be studied. The principal bodies to study from this viewpoint are the thyroid, hypophysis, and genital glands. In Graves' disease the psyche shows an abnormally high degree of affectability. The patient is strikingly irritable and restless, shy, easily disconcerted and diverted. His movements are characterized by a certain haste and want of steadiness. His moods alternate from depression to excitation. Hence on such a substratum psychoses readily develop. According to Ziehen these are of two different types. One is the acute hallucinatory confusion such as results from various intoxications, while the other appears to be a maniacal culmination of the natural tendency to excitation. In myxedema the psyche is affected in a measure exactly opposite. The affectability is greatly diminished so that the subject is quite indifferent to his surroundings. All mental processes are retarded. In order, however, to understand the relationship between the thyroid and the psyche one must begin with physiology. The developmental enlargement of the thyroid at puberty is well known, and at this period the psyche undergoes its mightiest transformation. During menstruation and pregnancy the organ also enlarges, and at these periods the emotional life is intensified. Again in senility with the blunting of the mental processes the thyroid undergoes atrophy. Certain writers even term the organ the "emotional gland," so manifest is its relationship to the affectability. But to explain this relationship few data only are available. Does the thyroid influence the nerve centers through the sympathetic? Or is thre an elective affinity between the thyroid products as they circulate in the blood and certain portions of the central nervous substance? Before attempting to answer these questions it is best to study some of the other glands. The article will be continued.

Tracheopathia Osteoplastica.—Haga had already reported a case of this affection, which consists of a deposit of cartilage and bone in the mucosa of the trachea. He gives another, a chance autopsy find in an elderly man. In his first case it could not be shown that the new formations were connected in any way with the tracheal rings. In the present one serial sections were also made, but again it was impossible to detect any continuity or other bond of community. Both patients died of cancer, and the first one had cancer of the thyroid. It is certain that the deposits occurred in a trachea, the seat of an inflammatory process, but beyond that all is conjectural.

Acquired Supersensitiveness of the Skin.—Sauerland who had been making a series of experiments on the degree of absorption of medicaments contained in ointments was led incidentally to the study of specific supersensitiveness of the skin. The test for absorbability was commonly a urinary one. Two substances tested were iothion and salicylic acid in various combinations. There was no congenital local supersensitiveness to any of the substances tested, nor was there any idiosyncrasy present toward them when given inwardly. But when a given area of skin had been treated repeatedly with the same preparation, an inflammatory reaction was finally induced. If a number of areas of skin were treated, some more and some less frequently, the anaphylaxis was manifested more severely in the area which had received the greatest number of applications. The more severe the reaction the shorter the incubation period, which ranged from one week to three or more. The author's earlier experiments were naturally made upon his own person and he was therefore in position to know that there was no peculiarity of any sort in the integument tested. After the experiments the skin remained sensitive to salicylic acid for over three months. The sensitiveness was clearly dependent on cumulative activity. Naturally these results suggest an entire series of future experiments of the greatest practical bearing.

Further Investigations into Anaphylatoxin and Bacteriotoxin.—Aronson refers to his earlier researches from which it appeared that many bacteria produce with guinea pig blood complement a virus which behaves in every way like an anaphylatoxin. From subsequent labors of his own together with much work since done by others in various fields of activity he concludes that bacteria alone are able to cause all cleavage processes with protein. Products are formed which may be highly toxic and which are in all respects the same as endogenous endotoxins. Hence in general infections not only are intoxications caused by the parenteral digestion of bacterial albumin, but the bacteria are able to cause the formation of toxins from the tissue proteids without any attempt at the formation of antibodies. The author's recent work with typhoid infection shows clearly that as far as that disease is concerned the substances which produce the anaphylactic reaction cannot be made to form immunizing antitoxins.

Influence of the Blood Glands on the Psychic Functions.—Münzer concludes his serial study with the following summary: The thyroid gland is of the first importance in expression of the affect life, this being shown by an entire series of physiological and pathological data. The posterior lobe of the hypophysis exerts a similar influence, while the anterior lobe exerts a trophic influence. The posterior lobe in addition to its influence on affect life may possibly be an independent center for the sexual impulse. The genital glands are the original seat of this impulse but also exert an influence on character and affect life. The pineal gland appears to antagonize the sexual impulse and, consequently, sexual maturity. All these glands therefore appear to stand in close relationship to the higher nervous centers and in virtue of this tie are able to modify the higher psychic life. At present there is no evidence that the suprarenals, parathyroids, and pancreas are able to exert a similar influence, hence these may not need to be reckoned with in connection with psychoses. The higher nervous centers may themselves produce an internal secretion. We know that in psychoses the blood glands sometimes appear to be involved secondarily, so that the possibility of reciprocal influence may be borne in mind.

Münchener medizinische Wochenschrift.

March 19 and 26, and April 2, 1912.

Appendicitis as a Borderland Disease.—Krogius writes in the interest of harmony between physician and surgeon in respect to the choice of treatment of appen-

dicitis. Himself a surgeon, he appears to find a ready way out of the dilemma without prejudice to either side. There is a benign appendicitis which is regular in course and shows no evidence of unfavorable progress, but instead the tendency is always to betterment. When the symptoms persist without tendency to improve the condition becomes a surgical one; and much more so is this the case where the evidence, however slight it may seem, shows a tendency to aggravation. Even a single symptom, become ever so little worse, indicates early operation. The prognosis is by so much graver, and need of intervention the more urgent when any one symptom becomes greatly aggravated, or when several unfavorable symptoms coexist. If after one attack resolution does not take place within reasonable time, when pain returns and does not abate again, or when a second attack of vomiting or a second chill occurs or when there is only persistent tenderness to pressure without tendency to lessen, it is as good as a diagnosis of impending gangrene or perforation and operation should not be deferred a day. No time should be lost through the palliative use of morphine. If the pain is severe enough for that, the condition is serious enough for operation. The author has now made use of these principles for seven years with a material of hundreds of cases, and in not one has his judgment been misplaced. If the conditions are balanced so evenly that a choice is impossible, one must operate, of course.

Tertiary Tuberculosis.—Hamberger believes that the infectious granulomata must exhibit a parallelism among themselves in respect to successive outbreaks and early and late lesions. He quotes Babes' opinion that leprosy as we know it clinically is practically a tertiary affection. The primary and secondary forms pursue a course so nearly latent as to escape notice. Tuberculosis must from analogy have its typical late lesions. Hence he does not look on pulmonary phthisis as representing the extended ravages of a local infection, but as a late visceral lesion of a systemic infection dating back for some years. Other late lesions comprise white swellings, some cases of bone tuberculosis, lupus vulgaris, renal tuberculosis, certain cases of tubercle of the eye, and types of hepatic cirrhosis and adherent pleurisy and pericarditis. This view is not merely the old belief that the greater part of tuberculosis in later life originated from childhood infection. A young child, an adolescent or an adult may contract the disease and in time show late lesions. The principal feature is the period of latency. The greater number by far of tuberculous victims are adults, just as are the majority of lepers. In either disease the period of latency may be as long as thirty years and is probably not much less than three. Syphilis behaves in the same manner. A particular type of delayed lesion is to be seen in certain fibroid affections. Here belong fibroid pulmonary phthisis, tuberculous cirrhosis of the liver, certain cases of adherent pleurisy and pericarditis, etc. Another type is characterized by promiscuous destruction of all tissues involved as in "white swelling" which involves bones, joints and tendons, and in nephritis.

Harmful Possibilities in the Use of Camphor.—Happich, having reference to the tendency to make use of large doses of camphor as a bactericide and analeptic, calls attention to untoward results which sometimes proceed therefrom. Some surgeons have thrown as much as 50 or 100 c.cm. of camphor oil into the peritoneal cavity after a laparotomy, and the belief has been freely expressed that camphor can do no harm. Even years ago Ziemssen stated that this substance "has no maximum dose." Nevertheless camphor is quite toxic to small animals, to the amount of one cgm. per kilo (three cgms. will kill a rabbit). Given as vapor and respired by the animal the toxicity is notably increased. The danger for mankind would lie in giving large doses to a badly weakened subject. The overaction of camphor is expressed ordinarily by marked slowing of pulse and tendency to collapse.

Relations of the Head to the Limbs.—Magnus discusses certain reflexes which he holds largely responsible for the maintenance of muscular tonus. He characterizes them as exquisitely tonic. There exists a sensory component which does not proceed from the sensory nerves of the muscles, and does not come into relationship with the reflex centers in the cord which nevertheless exerts a notable influence in maintaining muscular tonus. These elements proceed in part from the cervical region and aid in determining the position of the head on the trunk and in preserving permanently the muscular tonus of the lower extremities. Another course is the labyrinth, the relationship of which to muscular tonus has been extensively studied. The combined neck and labyrinth reflexes place the head in a certain definite relation with the limbs, whereby a certain movement of the head is associated with a certain attitude of the body. The labyrinth exerts a definite influence on the neck muscles. This subject has been studied both in the clinic and in animal experiment. Let us suppose that a child's head is in a definite attitude with respect to its trunk. The tonus of the individual limbs is determined and the position of the head now changed. After a variable interval the tonus in the limbs now shows a change. When the position of the head in space is changed, the alteration in tonus is called forth by the labyrinth reflex. When the position of the head on the trunk is changed, the alteration in tonus is due to the cervical reflex. It is evident that in various pathological states these reflexes will be found to be modified.

Röntgen Castration in Prostatic Hypertrophy.—Ehrmann refers to the experience in this field of Wilms and Posner and Hock, respectively. The author appears to have been the third to enter the field and thus far has treated but one case. Patient was nearly 60 years of age and had been found to present a much enlarged prostate with beginning urinary infection. He recovered readily through using a retention catheter. The uroseptic attacks continued, however, with suspicion of pyelitis. Severe hematuria was a feature of the case. Radiography of the testicle was then begun. After a short interval improvement began and continued steadily. The testicles diminished in size under the treatment. The prostate is much smaller and softer. The only symptom which persists is nocturnal desire to urinate.

Scopomorphinism.—Franck applies this term to a case of associated chronic addiction to scopolamine and morphine. Such a condition would be likely to come about only through the availability of a combined solution of the two principles. The patient was a male, 32, neurasthenic, upon whom an operation had been performed under scopolamine-morphine narcosis. He straightway began to use the narcotic mixture as supplied to the profession in ampullæ and continued the use for over a year. At first he injected one ampulla every evening, gradually increasing the frequency and dose until he was using three ampullæ thrice daily. The syndrome set up comprised emaciation, profuse sweats, general tremor, a high degree of mydriasis, constipation, marked increase in activity of the reflexes, and impotence. The characteristic stupor which develops after the injections would sometimes appear in their absence. The condition was purely psychic, however, for the subject instead of resting, pursued numerous activities automatically and without the least subsequent recollection of events. At last an equivalent state appeared to replace sleep so that the victim did impulsive, purposeless acts, such as seeking for supposed lost property. He was able to transact business behind the counter, but his affairs eventually suffered more and more. Of interest is the fact that the subject could not at any time tolerate morphine alone. He was readily cured within a month.

The Gurita.—Under this name Kolb describes the bandage worn by the Javanese women after confinement to preserve their youthful outlines. The Hollanders appear to have copied this custom from the native women and the European women have evidently borrowed the practice from their colonial sisters with slight modifications. As recommended by the author it is a wide corset reaching from the breasts to the mons veneris. The aperture is at the flank, in advance of the lateral line. The posterior flap has some ten tails or straps and is long enough to overlap the anterior flap. The margin of the latter is free, but in the opposite inframammary line a corresponding number of tails or straps is attached. When the bandage is in place the two sets of tails may be knotted together, or straps and buckles may produce the same effect. The underlying ideas may of course be carried out in a variety of ways, and such apparatus could readily be extemporized. The bandage appears to be soft and free from anything intended to confer rigidity. The author employs it in other conditions, and it may be applied during labor to increase abdominal pressure. It also makes a good abdominal support for pendulous belly. It cannot be claimed that the idea is in any sense new in Europe. Old accoucheurs used to apply towels in a similar fashion during labor. The bandage in common use immediately after delivery, and fastened with a series of safety pins, is not unlike it. The novelty doubtless lies in the wearing of it systematically as a prophylactic by a young normal woman.

Thrombosis of Arm Veins from a Blood Pressure Instrument.—Mohr describes a case of this peculiar character which tends to show that it is not absolutely safe to take pressures repeatedly in cachectic, bed-ridden subjects. The patient had caseous pneumonia of tuberculous nature and was very ill. The pulse was unusually good considering, ranging from 74 to 100 only although the fever ran high at times. On this account probably, readings were taken daily for two weeks. At first 132 mm. was recorded, but the figure sank steadily to 110. At this period it was noted that thrombophlebitis had developed in the median cubital vein. The process extended to the cephalic and basilic veins. The fact that a mild thrombosis also affected the veins of the left leg showed the strong element of predisposition which had been present, but the reporter had no doubt whatever that the arm thrombosis would never have occurred in the absence of the sphygmomanometry. The bandage had doubtless caused a minute endothelial lesion. The patient recovered alike from the thrombosis and pneumonia.

Deutsche medizinische Wochenschrift.

March 21 and 28, and April 4, 1912.

Chemotherapeutic Problems.—Blumenthal has for some years past studied the affinities of various chemical substances for the organs of the body from a two-fold viewpoint. First, by this means he has hoped to arrive at a knowledge of scientific therapeutics, and second, because light might be thrown thereby on physiological processes. For over a year he has worked with the aromatic arsenicals. It had been believed that many healthy animal tissues possess a decided affinity for arsenic but the author was unable to confirm this. On the other hand there seems to be an affinity on the part of arsenic for certain tissues in diseased animals. More recently he has studied mercurials from this viewpoint. The toxicity is naturally dependent on the solubility or ionisability of the combinations. When syphilis yields to mercuric bichloride only a trace of the latter is actually concerned in the reaction. When thus administered, as in hypodermic injections of solutions, mercury shows a notable affinity for the liver, and for no other organ. But if the metal is used in colloid suspension there is no affinity shown for the liver; the remedy is therapeutically weak because it is very promptly eliminated. It therefore appears that there is a direct relationship between an ionisable preparation, attraction for the liver with temporary sojourn in the latter, tardy elimination and therapeutic efficiency. But there is no parallel between organotropism on the one hand and toxicity or therapeutic effects on the other. Iodine has an affinity for cancer cells yet does not modify them in any way. This kind of organotropy may perhaps be of use in the future for transportation, or for displacing some active organotropic substance from an organ. For example iodine might be so incorporated in an arsenical molecule as to carry some of the arsenic into tumor tissue. Again iodine by displacing mercury from the hepatic cells might be made doubly efficacious in the treatment of syphilis if given after a period of mercurial treatment. If given side by side as in the mixed treatment, iodine doubtless weakens the action of mercury. This could be an advantage or drawback, according to circumstances.

Toadstool Poisoning.—Schurer states that our knowledge of this subject has been somewhat advanced by recent labors in Kobert's laboratory. Two poisons are now known to be active in these cases, an alkaloid and a hemolytic principle which is termed phallin and is believed to be a toxin in the narrower sense, i. e., a substance capable of forming antitoxins and against which animals may be immunised. A recent episode of mushroom poisoning in man has been studied in the light of the new discovery. An adult male who had eaten heartily of the fungi was seized at night with violent persistent vomiting, diarrhea and painful tonic muscular spasms in the calves of the legs, which eventually became generalized. The general reaction was not very marked. On the third day there was swelling of the liver which soon subsided. The urine showed no evidence of hemolysis or of destruction of the hepatic parenchyma. The wife and four children of the patient presented similar symptoms and all recovered save the youngest child, who in addition to the evident predisposition of youth had eaten very heartily of the toadstools. In this case there was absence of the usual incubation stage. The convulsions were very severe, clonic as well as tonic and were succeeded by fatal coma. In this case, therefore, the higher nerve centers were involved, as was abundantly shown by autopsy. The type was not that of encephalitis but represented purely a degeneration of the nerve cells. The fungus eaten was the amanita phalloides and the syndrome set up was typical of toadstool poisoning. There is not the slightest evidence of a hemolytic component in these human cases, save that there was slight icterus in one case and urobilinuria in another. The incubation period of ten hours or thereabouts is the sole feature which suggests a toxemia. But neither is the syndrome especially suggestive of alkaloidal poisoning. A complicity of two poisons seems involved and at present we can only assume that the alkaloid sets in motion some disintegrating process in virtue of which a secondary autointoxication results. As yet we have no rational or even empirical treatment of toadstool poisoning.

Treatment of Laryngeal Tuberculosis.—Killian states that this is a tertiary lesion, hence necessarily of unfavorable prognosis. He believes with Römer that the great majority of tuberculous adults were infected in childhood. Practically laryngeal tuberculosis represents an autoinfection from the lungs at the time at which a closed pulmonary focus opens. Other portions of the upper air and food passages are exposed, but the larynx is almost always the part to be infected. In making an exact diagnosis it is sometimes advisable to inject morphia subcutaneously in addition, of course, to the use of local anesthetics. Brüning's magnifying laryngoscope also facilitates examination. Not every consumptive who is hoarse is a victim, although some of them may have suffered and recovered spontaneously, for

mild and benign cases are known to occur. There is also a class of suspects who present equivocal lesions in the larynx to the mirror. If the lungs also show evidences of the disease the suspicion is much intensified. However, the disease does not develop in the larynx, although there may be a possibility of arrested development. Such cases are probably encountered chiefly by the inexperienced laryngoscopist. The general principles of treatment remain much the same as they were a generation ago in regard to cautery, excision, laryngo-fissure and extirpation and it remains only to consider the value of new discoveries in this field. Radiography and solar rays have a favorable action and may be used as accessories. Galvanocaustic deep puncture, introduced by Grünwald in 1907, has been found of value by the writer in cases with much infiltration. He has no doubts whatever that there is a hematogenous form of the disease; in fact, he has almost witnessed the evolution of miliary nodules on a healthy looking mucosa. If there is any suspicion of this component in a case it is best not to attempt anything radical until the case has been watched.

Treatment of Surgical Tuberculosis with Tuberculin.—Rosenbach uses the tuberculin which goes by his name both for diagnosis and treatment. He reports 48 cases of a miscellaneous character—tuberculosis of bones, lymph-nodes, serous membranes, and skin. His method may be illustrated by a case of very severe and disfiguring nasal lupus in a child. Patient otherwise healthy. She was treated with tuberculin and the curette. The lesions healed promptly, but showed a notable tendency to recur *in situ*. The recurrences, however, were progressively less prompt and extensive and finally ceased. The patient had been under treatment over two years and made a fair cosmetic recovery.

Collateral Activity of the Peristaltic Hormone.—Hesse refers first to the early work of Zuelzer, who studied the peristaltic hormone for two years before pronouncing the latter absolutely safe in practice. He admitted that it might cause slight nausea, vomiting, and temperature rise (hormone fever). Other investigators verified his statements fully in these particulars. The author, however, is compelled to take issue with them all in the matter of the safety of the preparation as it occurs in the markets. Dittler and Mohr have described a case of serious collapse from an intravenous injection, the blood pressure falling from 125 to 100; so that it was necessary to give camphor as an analeptic. Investigation has since shown that the blood pressure always falls after these intravenous injections, even in very small dosage. In other words this is the really typical feature of its action. Kretschmer has also reported a case of collapse requiring the use of adrenalin and saline infusion. Finally the present writer adds the third case. Collapse occurred during the injection and was very severe in character. The possibility of anaphylactic shock in these cases may be excluded. In the absence of complete data the author concludes that if a patient has at the outset an abnormally low blood pressure, the hormone produces collapse by acting merely in the normal fashion. Hence a reading should always be obtained just before the remedy is to be exhibited. There is another factor in evidence. The commercial preparations cannot be standardized and do not always represent one and the same substance. Popielski has shown that they exhibit considerable variation in their action on the blood pressure.

The Neisser-Seibert Lues Prophylactic.—Sklepinski recalls the fact that two years ago the two authors published a fat free ointment for inunction after coitus or other possible exposure to syphilis. The only bactericidal substance was mercuric chloride, the other ingredients comprising starch, tragacanth, gelatin, alcohol, glycerin and water. It appears that a preparation represented to be the foregoing has been placed on the market under patent rights. Those physicians who believe in practising medicine with "package goods" will be interested in learning the success of this idea in the present case. Since stability and low cost are of first importance the author has investigated the specimens obtained from the viewpoints of permanence and fidelity to the published formula. The proprietary was found to be faithfully prepared. The author also had prepared an ointment from the original recipe and compared it with the market specimen. Both ointments were found to be unstable on standing, and this was readily shown to be due to too much alcohol, the content of the latter being 25 per cent. By the simple expedient of substituting 10 per cent. of glycerine at the expense of the alcohol the ointment became permanent. The modified formula is as follows: Take tragacanth pulv. 2, glycerin 27, and mix. Then add gradually, warming, sodium chlorate, 1, amylum tritic. 4, gelatin alb. 0.7, distilled water 50. Under continued stirring, and allowing the mass to cool add sublimate 0.3 dissolved in alcohol 15, and finally add enough distilled water to make 100 grams of ointment.

Treatment of Acute Peritonitis.—Henri Hartmann believes that in the treatment of acute peritonitis medical treatment has now no place. Cathartics should never be given and there is no advantage in waiting until acute conditions of infection have arisen before operating. Diagnosis must be early and precise, and should be followed by rapid and simple operation, the aim of which should be to destroy the original focus of infection and to empty the abdomen of most of its toxic and infectious contents, while trusting to the absorptive powers of the peritoneum to remove the rest. If drainage is employed the tube should descend to the bottom of Douglas' cul-de-sac.—*Annales de Gynécologie et d'Obstetrique.*

Local Anesthesia of the Uterus with Cocaine.—F. Febres advocates the performance of many operations on the cervix, both in gynecology and obstetrics, with local anesthesia by means of cocaine. The application of the cocaine is interstitial, and is made by four injections into the cervical tissues: in front, behind, and on the sides, with an amount of solution which will equal four centigrams of cocaine. In four or five minutes there is perfect local anesthesia. This method is applicable in all operations on the cervix: repair, incision of cysts, dilatation for treatment, curettage, and prolapse operations may all be done in this way. After labor the removal of adherent membranes and dilatation for rapid evacuation of the uterus may be done.—*Press Medicale.*

Radium Treatment of Cancer.—Dominici describes the different modifications of radium therapy in various forms of malignant growths, according to their nature and location. Not only superficial skin cancers, but also deep-seated growths are susceptible to the action of radium if the radium is properly placed. The tubes may be applied on the surface of the skin, in the natural cavities of the body, and in the substance of the growths themselves. With the author the use of radium has become a precise and definite agent. It cures many cases of both superficial and deep cancer; in other cases it causes marked improvement; and finally it renders operable certain inoperable cases of deep cancers. When the knife can easily and thoroughly remove a growth radium should be put aside; in some cases it should be simply an aid to surgery; and in still other cases in which a surgical operation is contraindicated it should take the place of operation. The author has studied histologically the method of regression of the tumor under the influence of radium; the process of regression is purely local, and in many cases it is aided by general processes such as are produced by ferments and toxins according to Coley, and by hypochlorites, according to Becker.—*La Riforma Medica.*

Insurance Medicine.

Medical Aspects of Life Insurance.—Sir Richard Douglas Powell in a series of three lectures delivered at the Middlesex Hospital, London, discussed the medical aspects of life insurance. It is pointed out that in no development of social science has medicine taken a greater part than in that of life insurance. In Great Britain, of the three factors upon which modern life assurance is based, the Registrar-General's returns of births and deaths, the census, and the prospective value of capital at compound interest, the first and in part the second largely depend upon modern data.

There is another aspect in which the relation of medicine to life assurance is important. Preventive medicine, in which not only expert health officers, but all practitioners in the kingdom, are zealously engaged year by year, diminishes the number of deaths from preventable diseases, and so by increasing the duration of life adds to the aggregate value of policies of insurance. Improved medical and surgical practice has told in the same direction.

Powell gives a brief sketch of the history of the origin and development of insurance reckonings. The first records of mortality ever published were collected by Captain John Graunt, F.R.S., during a period of twenty years while the plague was raging in England, and issued in 1662. Edmund Halley, the great astronomer, in 1693, presented to the Royal Society a study of the "Degrees of the Mortality of Mankind." At that time there was but one city of Europe in which a record of the age at death was kept, the city of Breslau in Silesia. Halley obtained the records from that city for five years, 1687-91, which included 6,193 births and 5,869 deaths. He made an estimate of the population at 34,000 and constructed a table showing the number of persons who will die annually from the age of one year onwards. Halley draws many ingenious and valuable deductions from this table, which is of historic interest as the first mortality table.

Marine insurance was the first in the field of business insurance at the beginning of the seventeenth century, and about 1638 the insurance transactions, which consisted in the underwriting of individual ships at risk on the high seas, were conducted at a certain Lloyd's Coffee House in the city of London, whence the name now universally associated with such risks was derived. Fire insurance next took the field in 1680, stimulated from small isolated ventures by the disasters of the Great Fire. It was more than three-quarters of a century later before life insurance except in the form of annuities was definitely established. A Frenchman, an Englishman, and a Dutchman went somewhat further into the matter than Halley, and in 1780 Dr. Price, living in the district of Northampton, analyzed the death registers of a certain parish of All Saints extending over a period of forty-six years, and compared them with the population, which he estimated from the baptismal entries and calculated therefrom the expectation of life, which he formulated in a table known as the "Northampton Table of 1780." This table was for nearly thirty years the basis for actuarial calculation of life assurance. In 1815 a somewhat similar calculation was made from the deaths that occurred in nine years out of an estimated population of 16,350 persons living in two parishes of Carlisle and formulated in a table, known as the "Carlisle Table."

Life assurance as a practical business commenced with the issue of policies by the Equitable Society of London in 1762.

According to Powell Great Britain is the birthplace and was for long the home of actuarial science, and therefore he restricted his observations to British insurance, although as he remarks, insurance societies soon made their appearance in Germany and America and in other countries. Up to the beginning of the nineteenth century the estimates of the general population of Great Britain were only obtainable by calculations based upon records, imperfect as they were, of baptisms and burials. The first census was taken in 1801, and since then has been renewed every tenth year. The reports of the Registrar-General first appeared in 1838, giving a careful analysis of the civil state of the population as regards marriages, births, deaths, occupations, etc. But the causes of death were yet only imperfectly certified, and it was not until 1874 that medical certification as to the causes of death was made compulsory. The Nomenclature of Diseases, instituted by the Royal College of Physicians, first appeared in 1869, giving a much increased uniformity and precision to the certificates of death. Powell dissects the composition of the modern actuarial table and of the Registrar-General's Table from which it is constructed. Powell thinks that a consideration of actuarial tables in Great Britain during the past decade suggests a marked improvement in the general health of the population, and does not lend support to the gloomy views now prevailing of the degeneracy of the British race. He also draws attention to the fact that unless the door of a life assurance office were well guarded medically all bad and doubtful lives would soon begin to pour in and bring the society to inevitable grief.—Lecture I., *The Practitioner*, April, 1912.

Tropical Risks.—H. Braun continues his study of this subject. He says that at present no separate premium table is necessary for tropical risks, but merely an extra premium should be charged according to the special dangers in certain tropical countries. Such tables of extra premiums have been constructed in the past and Braun reprints most of them. He repeats that not everyone who enjoys good health at his home may expect to have equal good fortune in the tropics. Certain physical conditions should count very much against removing to the tropics. Among them are various nervous states, sleeplessness, tendency to headaches, and irritability; disturbances of digestion and tendency to diarrhea or constipation; repeated attacks of appendicitis; heart disease, anemia; alcohol habit and excessive use of tobacco; morphia habit; deafness, inflammation of the auditory organs; nasal obstruction; repeated attacks of gout or rheumatism; renal disease of any nature; diabetes; pulmonary affections of any sort, that predispose the patient to tuberculosis; tendency to skin disease; existing venereal disease.

The best age for acclimatization is 26 to 30 years. Younger and older persons usually suffer more than persons between these ages. An applicant for insurance who expects to remove to the tropics should be enjoined to have his teeth put in good order and to try the effect of taking about fifteen grains of quinine. If this quantity of quinine produces marked untoward symptoms, beyond slight ringing in the ears, the applicant should reconsider his intention of life in the tropics. He should also be re-vaccinated if more than three years have passed since his last vaccination.—*Zeitschrift für die gesammte Versichcrungs-Wissenschaft*, March 1, 1912.

A HOME FOR AGED PHYSICIANS.

By HEINRICH STERN, M.D.,

NEW YORK.

I HAVE often put the question to myself: Is the New York Physicians' Mutual Aid Association doing all it can for its members when one considers its potential ability? How glad I would be if I could answer with an unqualified "Yes." It is a matter of great regret to me, in one point in particular, that we are not doing our duty. True enough, the insurance rate for the last few years has been comparatively low, but some insurance associations, fraternal and others, charge still less. Of course, our association has a better financial standing than any other similar institution in the State; however, the ultimate outcome of all assessment insurance will be fewer new applicants from year to year, fewer applicants in proportion to the then existing number of members.

The New York Physicians' Mutual Aid Association, in order to be kept alive and growing, and also for moral reasons, should try to offer a little more than the mere pittance of one thousand dollars, paid to those who are left behind by the death of a member of the Association.

This member himself had practically received no benefit whatever from this Association during his lifetime; and most young practitioners of this day, no matter in which way they are approached, are reluctant to join this body under the mere assumption that their prospective descendants will reap the benefit of his annual outlay. They would join, however, if something tangible were offered them for their own personal benefit.

Many of the fraternal orders and trade unions have their own homes for the aged and infirm. There are homes for old soldiers, a snug harbor for sailors, a home for worn out actors, and we even consider the animals which have served their masters conscientiously. But the physician who has labored conscientiously for humanity, and who, as we all know, rarely can lay by a store of worldly goods, and perhaps has no children on whom he can depend for sustenance in his old age—where is there a home for him? Nowhere! There is not a single place in this vast and wealthy country of ours where he can spend the last days of a busy and devoted life in careless retirement, free from worry, and in the company of his equals—his professional brethren.

It is not the business of the American Medical Association to found such institutions, for this body must accept as a member every physician "in good standing" in his respective State society; and what "good standing" in such associations is we all know. Should the American Medical Association, or any State association, ever attempt to establish a home or homes for aged or infirm physicians, it would soon find it a financial impossibility.

The New York Physicians' Mutual Aid Association, on the other hand, with its selected membership, which is confined to the State of New York, can very well afford to establish a small home for the possible fifteen or twenty dependents which a membership of 2200 would probably thrust upon it.

A farm, for instance, in Putnam or Dutchess county—a farm of one or two hundred acres with good buildings sufficient to give shelter to twenty inmates and five or six servants, may be bought at any time for a sum not exceeding ten thousand dollars. This farm would give welcome occupation to some of the inmates, while others could act as superintendent and in other official capacities. Many, if not all, the foodstuffs could be raised on this farm, and the cost of maintenance, including all the wages, should not exceed forty-five hundred dollars for fifteen inmates. One additional two-dollar assessment would defray the entire running expense for one year. Such an additional assessment would be gladly paid, I am sure, by every member of the Association. Furthermore, each member upon entering the home would surrender his policy, or any part of his claim, to the Association and its Home.

The purchasing of such a farm must, of course, be done by voluntary contributions. If a hundred members or charitably inclined non-members obligate themselves to pay one hundred dollars apiece, the necessary funds would accrue very quickly. I, for one, pledge one hundred dollars, or more if necessary, for this purpose.

Such a home may, as a matter of fact, be demanded by every member of our Association. They need not consider it a charity, for each member has contributed his share toward its support for years. Each member is rightfully entitled to a place in the Home. He is simply receiving the benefit of his contributions to the Association while he is alive, instead of some of his relatives after his death.

"Where there's a will there's a way."

Gentlemen, this institution is needed—is needed to calm the despair of the old physician and his wife—is needed for the gentle but now decrepit old doctor who has dried many a tear, but was not sufficiently callous to make the extraction of dollars from a suffering clientèle his only purpose in life. With starvation staring him in the face the old doctor very often terminates life in a manner which I may term "accidentally on purpose."

Mr. Chairman and Members of the Board of Directors: It is not an unsurmountable task to establish a home for our aged and infirm members, and now, Mr. Chairman, I ask you to submit this question to the Board of Directors, and I move that a committee of three be appointed to consider the feasibility of establishing such an institution.*

250 WEST SEVENTY-THIRD STREET.

*The motion was carried unanimously, and the Chairman appointed as members of this committee Dr. Heinrich Stern of Manhattan, Chairman; Dr. A. Edward Davis of Manhattan, Secretary, and Dr. Edward H. Squibb of Brooklyn; Dr. William F. Mittendorf, President of the Association, is to be a member ex-officio.

Address to the Board of Directors of the New York Physicians' Mutual Aid Association, February 13, 1912.

Typhoid Fever in Nurslings.—A. Brelet notes that typical typhoid fever in infants is rare, although the infection is rather frequent and of grave import. It is characterized by continuous fever, digestive disturbances, sometimes severe meningitic symptoms, purpura, convulsions, intestinal hemorrhages, etc. There may be no ulceration of Peyer's patches or solitary follicles, but hemorrhage may occur from the intestinal walls. The spleen and mesenteric glands are enlarged. Rose spots may be present, but are usually absent. Owing to the irregularity of the course of the disease the diagnosis is often not made; the Widal reaction is not always present, but bacteriological examination of the feces shows the bacillus of Eberth. Bronchopneumonia may be a prominent symptom. The disease is exceptional during the first six months of life; if it occurs in the mother during pregnancy the infant generally dies *in utero* or it may live but a few days. The child may be infected by the mother while at the breast or by a nurse.—*Gazette des Hôpitaux.*

Book Reviews.

Tumors of the Jaws. By Charles L. Scudder, M.D., Surgeon to the Massachusetts General Hospital. Octavo of 391 pages, with 353 illustrations, 6 in colors. Cloth, $6.00 net; half morocco $7.50 net. Philadelphia and London: W. B. Saunders Company, 1912.

The practice of writing monographs covering a limited and well-defined subject has much in it to be commended and encouraged. The writer's interest is apt to be more active, for he is not mentally exhausted as he would be in attempting to produce a long text-book on the whole of surgery. The material is apt to be his own and his individual judgment is more frequently and freely expressed than in a formal and more elaborate treatise intended to cover all aspects of a large question. It is with especial interest, therefore, that we have examined this handsome volume on tumors of the jaw. It is excellent in many respects. The illustrations, some 353 in number, are many of them entirely new, and those which have been borrowed from other works are selected with judgment and intelligence. One suggestion might be made, and that is that the deformities produced by tumors of the face are so hideous that even in a volume not generally accessible to the public it might be well to limit as far as possible reproductions of the advanced types of malignant disease. They are much less instructive than the pictures taken at an earlier stage and are not at all useful in diagnosis.

The microphotographs of morbid tissues are, in general, good, and give very well all important points. One seems to illustrate very successfully the use of such reproductions as a matter of record. On page 119 there is a case reported of sarcoma of the lower jaw, followed by carcinoma and extension to the lymphatic glands. Without venturing to presume to doubt the diagnosis of sarcoma it is quite certain that the microphotograph, which is probably selected to illustrate a typical portion of the growth, shows nothing more than some granulation tissue infiltrated with numerous leucocytes and does not in any way demonstrate the characteristic morphology of a sarcoma. Indeed, the clinical history of the case rather suggests that this growth may have been one of the soft epulides of the jaw, and that the carcinoma developed entirely independently and at a later stage. Except for such minor points the pathological side of the book is satisfactory and is of a type which will be useful to the surgeon. It is very satisfactory to note that in the first chapter, on epulis, the absolute clinical harmlessness of these growths is so firmly insisted upon. Much confusion has resulted from the loose designation of these tumors as giant-celled sarcomata and the assumption by the surgeon that a large portion of the jaw must be resected in order to prevent recurrence, whereas in many cases a very moderate removal of bone will guarantee the patient against recurrence of the trouble.

A very good chapter is the one on the tumors arising from vestiges of the teeth, such as the odontomata and the dentiferous cysts. The condition is so rare that but few persons have an opportunity to study many cases, and the admirable illustrations give a better picture than any text with which the reviewer is familiar. There is a very satisfactory chapter on the tumors of the palate, including that peculiar group of growths known as mixed tumors. The methods of supporting the jaw after extensive resection are quite fully treated.

Dr. Scudder is to be congratulated on the production of a most successful study of an interesting surgical and pathological field.

Fourth Report of the Wellcome Tropical Research Laboratories at the Gordon Memorial College Khartoum. Volume A. Medical. Andrew Balfour, M.D., B.Sc., F.R.C.P. (Edin.), D.P.H. (Camb.), Director. Fellow of the Royal Institute of Public Health, the Society of Tropical Medicine and Hygiene, and the Incorporated Society of Medical Officers of Health; Member of the Association of Economic Biologists, etc. Published for Department of Education, Soudan Government, Khartoum, by Baillière, Tindall & Cox, London. New York: Toga Publishing Co., 1911. Price $5.00.

In this handsome volume of 400 pages are embodied the results of the recent labors of the small but energetic company of scientists who are doing such excellent work on the banks of the Blue Nile. The report is in two volumes, of which the present is devoted to medical research, while the other deals with general science. Over thirty contributions are presented, nearly all of them of the highest possible interest from the standpoint of tropical medicine. As is to be expected, very many of them have to do with blood infections of different sorts, due to trypanosomes or other protozoan parasites. An article of especial value to all laboratory workers is one by the director on fallacies and puzzles in blood examination, in which the artefacts that so often lead astray beginners and even more advanced workers are discussed and excellently illustrated. Other papers of particular interest are on the water supplies of tropical towns, on the fevers observed in the Sudan, on the treatment of kala azar with salvarsan, on diphtheria in the tropics, on tropical sanitation, and on mosquitos and malaria. The mechanical execution of the volume is remarkably fine and the very numerous colored plates, maps and photographs deserve the greatest praise. While the report will probably appeal chiefly to the rather limited circle of readers who are directly concerned with tropical medicine, for all of these it will prove of the utmost interest and value, and they will feel deeply indebted to its authors for the devotion with which they have accomplished wonders under the most difficult and trying circumstances.

Diseases of the Skin and the Eruptive Fevers. By Jay Frank Schamberg, M.D., Professor of Dermatology and Infections Eruptive Diseases in the Philadelphia Polyclinic and College for Graduates in Medicine. Second edition, revised, fully illustrated. Cloth, $3.00 net. Philadelphia and London: W. B. Saunders Company, 1911.

Dr. Schamberg is well known to medical readers as a writer of distinction and authority on the subjects with which this volume deals. It is eminently suitable that diseases of the skin and the eruptive fevers should be considered together, and the promptness with which a new edition of the book has been required shows that the plan has met with general approval. Among the subjects in which new matter has been introduced are sporotrichosis, grain itch, a peculiar form of pediculosis described by the author in 1901 and 1909, vaccine therapy, and the use of carbon dioxide in treatment. The recent developments in the treatment of syphilis and the Wassermann reaction are also detailed. The truly remarkable collection of photographs with which the work is illustrated has been added to and forms one of the most useful features of the book. The only omission of note that occurs to the reviewer is the absence of any mention of Brill's disease, concerning the status of which it would be interesting to have the views of so experienced an observer as the author. It is hardly necessary to emphasize the unusual excellence of the book, which has already acquired a high place among the treatises on dermatology.

Delayed and Complicated Labor. By Robert Jardine, M.D. Edin., M.R.C.S. Eng., F.R.F.P. & S. Glas., F.R.S. Edin., Professor of Midwifery in St. Mungo's College, Glasgow; Obstetric Physician and Gynecologist to the Glasgow Maternity and Women's Hospital, Glasgow; Examiner in Midwifery and Gynecology to the Scottish Conjoint Board, and also to the Victoria University, Manchester; formerly Examiner to the University of Glasgow; late President of the Glasgow Obstetrical and Gynecological Society; Author of "Clinical Obstetrics" and a "Practical Text-Book of Midwifery for Nurses," etc. With one hundred and seven illustrations and three colored plates. Price $3.00 net. New York: William Wood and Company, 1912.

This is a small book, but one which can be cordially recommended to students and practitioners alike. It contains the result of the very extensive experience of the author and is, throughout, a record of personal work and not a compilation. It is concise and well written, admirably arranged and clearly printed; above all, it is trustworthy.

Handbook of Mental Examination Methods. By Shepherd Ivory Franz, Ph.D., Scientific Director and Psychologist, Government Hospital for the Insane; Professor of Physiology, George Washington University. With 33 Figures and Diagrams. Price $2.00. New York: The Journal of Nervous and Mental Disease Publishing Company, 1912.

Dr. Franz's monograph consists of twelve chapters on the methods of examination of a patient in reference to sensation, movement, speech and aphasia, attention, apprehension and perception, memory, association, calculation ability, time of mental processes, and general intelligence. An endeavor has been made to select the simpler yet adequate methods of examination which require neither elaborate apparatus nor any special and difficult technique. Any additional information sought by the reader can be found in books and articles of reference named after each chapter. The monograph is very well written and should prove of value and interest to neurologists and to internists as well.

Society Reports.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

One Hundred and Sixth Annual Meeting, Held at Albany, April 16, 17, and 18, 1912

(Special Report to the MEDICAL RECORD.)

GENERAL SESSION.

(*Continued from page 788.*)

The Prevention of Deafness and the Instruction of the Deaf Child.—Dr. G. HUDSON MAKUEN of Philadelphia, Pa., read this paper. He stated that deafness was a much more serious affliction than blindness; in blindness but one corticalcenter of the brain was affected but in deafness two were useless. In blindness touch could be substituted for sight but in deafness no such substitute had been discovered. Good hearing was an absolute necessity. In deafness the corticalcenters showed atrophy. Dr. Makuen considered his subject in three parts: 1. To what extent blindness was preventable. 2. How it was preventable. 3. What could be done for children irrevocably and irremediably deaf. The great obstacle in the prevention of blindness was the almost fiendishness of the insidiousness of the affection, coming on as it often did before the patient or the physician was aware of it. He believed that 50 per cent. of deafness was preventable. There was, however, no specific recipe for prevention until the race had reached perfection. There were two kinds of deafness, congenital and acquired, the latter being the result of disease. The first could be prevented by strict application of the principles of eugenics. It was said that 50 per cent. of this type of deafness was due to consanguinous marriages. Acquired deafness might be primary or secondary. The most immediate cause of deafness was inadequate ventilation of the tympanic cavity and causes leading to this should be combatted. The greatest preventive lay in securing normal nasal breathing and palatal efficiency. It has been said that two-thirds of deafness resulted from measles and scarlet fever. Was it too much to hope that with modern knowledge these infectious diseases of childhood might be diminished. The day had passed when the practitioner could overlook complications of this nature; he must know the right thing to do and when to do it. Pain was the danger signal and in nine out of ten cases paracentesis the measure demanded. The key to the situation in the matter of the prevention of blindness was in the hands of the general practitioner. Dr. Makuen then considered educational methods applicable to the deaf but said that it should be remembered that deafness did not imply mental enfeeblement. The deaf child should not be classed with the mentally defective. Those but slightly deaf should be instructed in classes with normal children; those of greater degrees of deafness in special classes. The instruction of the deaf child should begin at home under the direction of an intelligent mother or governess and a physician as frequently the deaf child was not as far developed at the age of seven years as the normal child of two years.

The Prevention of Blindness and the Instruction of the Blind Child.—Dr. G. E. DE SCHWEINITZ of Philadelphia read this paper. He referred to a few conspicuous types of acquired blindness and chiefly to the ravages of ophthalmia neonatorum. He pointed out that while there were no complete statistics showing the prevalence of ophthalmia neonatorum, an approximate idea could be obtained by studying the admissions to schools for the blind, and in any list of carefully tabulated causes of blindness this disease far exceeded in potency any of the other etiological factors, the percentage of blindness from it being approximately 36, rising in some countries to fully 40, and rarely if ever falling below 25 or 26. In order to illustrate the economic loss from blindness from this source, the essayist showed that the annual expenditure of public funds for the blind in excess of the cost of educating seeing children in public schools in Massachusetts, New York, Ohio, and Pennsylvania was about $150,000. From these figures it was evident that the cost of blindness throughout the entire United States must be enormous. Many schemes for the elimination of this preventable disease had been brought forward, and Dr. de Schweinitz discussed the punishment by law of offenders against properly constructed legal regulations and compulsory prophylaxis. Concerning education he pointed out while this necessarily concerned most intimately the midwife, nurse, and other persons having charge of a new-born child, medical students should be carefully instructed in the dangers of the disease and in their responsibilities in obstetric practice in this respect, and doctors all over the country should be urged to join in an effort to secure the passage by legislative assemblies of needed laws which might be enforced by local boards of health. He further discussed the importance of education among women living in poor districts who were the mothers of families, and described the methods adopted in this respect by the Health Committee of the Philadelphia Civic Club. Concerning compulsory prophylaxis and the free distribution of a prophylactic, Dr. de Schweinitz pointed out that the frequency of ophthalmia neonatorum had diminished since the introduction in 1881 of the Crede prophylactic treatment, that this treatment either in its original or modified form was often, and perhaps always, necessary in all large institutions where poor women are assembled for the purpose of giving birth to their children, and where prior to birth it had been impossible to remove the danger of infection. Unfortunately, in spite of the existence of laws compelling the reporting of ophthalmia in various States, they are not actively operative in many of the States, notable exceptions being Massachusetts and Ohio, where it had been possible to secure prosecutions when there had been failure to give notification of ophthalmia neonatorum. Dr. de Schweinitz pointed out that while all of the present laws contained some good provisions, a satisfactory uniform law containing all such provisions as registration of births, instruction on ophthalmia neonatorum, reporting of cases by midwives, parents, nurses, physicians to health authorities, control of midwives, and free medical attendance, was most desirable. The writer of the paper also discussed the history and ravages of trachoma and the methods employed by the immigration officers to check the entrance of this disease into our country. He commended the ocular examination of school children because it enabled the physicians in charge of this matter early to detect the presence of contagious and other diseases of the eye, notably phlyctenular keratitis, and also to detect the refractive anomalies and to urge their correction in order that the ravages of eye-strain might be averted. Referring to the care of the blind child, he agreed with those who maintained that inasmuch as blind children were at least two years behind seeing children of identical age, the education of these afflicted ones must begin early, if possible in the homes from which they come. He pointed out that it was a mistake to believe that the loss of any special sense itself improved remaining senses, and showed that in point of fact the loss of sight tended, if anything, to make other senses less sensitive. He urged, however, a more thorough study of pupils in institutions for the education of the blind, and urged also that this kind of education would be materially helped if there was an appeal to the principles of modern psychological research. Such psychological researches might furnish certain data which would help to solve the vexed question as to the best alphabet for the blind, and would certainly help to decide whether the mentally deficient or the backward blind child should or should not be included in the general classes of blind childdren. Discussing the education of the blind still further, the essayist pointed out that in the best regulated schools for the blind the fundamental motive in teaching made an appeal to the motor centers. It was shown how by reason of practical and industrial education wide fields of usefulness have been opened to blind children. The over-cautiousness of the blind was described, and it was shown that this was in largest measure best controlled by developing among blind children a love of and an activity in athletic sports. The various occupations of the blind and the methods of instruction were described, and the method of training fundamental muscles before the finer accessory muscles are brought into action was also discussed. The higher education of blind children and their ability to enter advanced courses with seeing children were referred to. The essayist illustrated his remarks with numerous lantern slides showing the method of teaching, etc., in the Pennsylvania Institution for the Instruction of the Blind at Overbrook.

Second Day—April 17, 1911.

THE PRESIDENT, DR. WENDELL C. PHILLIPS, IN THE CHAIR.

Annual Oration in Surgery: The Duty of the Family Physician in the Management of Surgical Cases.—Dr. JOHN M. T. FINNEY, Professor of Surgery at Johns Hopkins University, Baltimore, Md., made this address by invitation. He considered his subject from the standpoint of the patient, from that of the physician, and from

that of the surgeon. It was to the glory of the profession that its individual members, with few exceptions, had always stood ready to sacrifice their own interests to those of the patient. There were instances where the interest of patient and physician conflicted as when a physician had under his care a wealthy patient, and the question arose as to whether some one else might not do more for that patient than he was doing. In such a case should he ask for a consultation or bluff it out and trust to luck? When the question of the selection of a surgeon arose the general practitioner was in the nature of things better fitted for this than the family. It was necessary, however, that he should have a knowledge of surgery and all that it involved. The time had gone by when they could belittle the surgeon. It was also obvious that no surgeon without a thorough training should attempt to practise surgery. The man who was not efficient might meet with success in a fair percentage of cases, but he was apt to go far and then meet with disaster. He quite agreed with the belief that was growing so general that the hospital was the only place in which to be surgically sick. This was true provided the surgeon in the hospital was competent. Hospitals were multiplying so rapidly everywhere that there were many without skilled surgeons. There was not the same feeling of responsibility in a hospital as in a home, and the surgeon was tempted to do things and take risks that he would not take if he alone were responsible. The most elegantly equipped operating room might be the place of heinous surgical crimes. The moral was that surgery should be restricted to the trained surgeon. There was no royal road to surgery; it could not be acquired in a ten days' course, or just by watching some one operate. The family physician should not attempt to operate, as both his judgment and his execution were at fault. He was also putting himself in a wrong position before the community; he should not put himself in a place where he could not defend himself in court before a jury; in a place where he could not prove that he was competent to do the work he had undertaken. The question then arose as to whether the general practitioner should act only as a "barker" and "catcher" for the surgeon. Only a small percentage of the cases coming to the general practitioner were surgical, so that referring them to the proper surgeon could not appreciably affect his income. On the other hand, the surgeon should follow the golden rule and not so deplete the finances of the patient that nothing was left for the family physician. After denouncing fee splitting Dr. Finney said that the family physician gave valuable services when he helped in the selection of a surgeon, when he gave that moral comfort and support which a family needed at such a time, when because of his acquaintance with the financial affairs of the family he arranged for the compensation of the surgeon. The surgeon should make clear the value of these services to the family. In regard to the responsibility for the after-care of surgical cases there should be no division of responsibility; the surgeon was responsible. On the other hand, the family physician should not interfere with this treatment by ordering favorite remedies or failing to comply with the directions of the surgeon. Since the making of an early diagnosis was so important in many conditions it was necessary that the family physician should be an expert diagnostician. He should not delay too long in calling in a surgeon. "Surgery should be a last resort but never a late one." There were two types of practitioners, those who regarded themselves as the servant of their patients and those who regarded their patients as so much material to be manipulated for financial gain. The trouble was that there was a plethora of physicians and too many unfit to practise their profession. In regard to the physician's duty at the time of operation, Dr. Finney said that he should by all means be with the patient at the time of operation, both because of his psychic influence on the patient and because he could not afford to miss an opportunity of confirming or revising a diagnosis. Too frequently the surgeon limited his services merely to the performance of an operation, leaving the after-care to others; this practice was not to be commended. They would have to overcome the notion that surgery was simply carpenter work. After the patient left the hospital there was often a long period during which the family physician could be of the greatest service in making complete recovery possible. The tactful physician could guide a nervous patient through this period of convalescence as well as it could be done by sanatorium treatment. The question of fees had to be considered and there was no doubt but that the surgeon frequently charged fees out of all proportion to the services rendered. The surgeon should see that the family physician got his deserts by showing the family his value. These criticisms were meant in good faith, and it was their duty to face facts as they were. If the profession did not recognize these failings and correct them itself it would soon stand convicted before the public. After speaking of the needs of the higher educational standards Dr. Finney urged those who held professorships in medical colleges to set an example of higher professional honor by refraining from exploiting their offices for the purpose of making money.

Oration: The Benefits of Vivisection to Mankind.—Dr. Walter B. Cannon, Professor of physiology, Harvard Medical School, Boston, Mass., made this address by invitation. He said in part that there were two ways open of obtaining a knowledge of nature: one was merely to watch events as they transpired naturally; the other was to arrange the environment and to watch the effects of this controlled environment. You might simply plant a grain of wheat and watch it grow or you might plant it so that you could regulate the amount of light, moisture, wind, heat, etc. The latter method was the scientific method. The cautious person put explanations, however plausible they might be, to the test before he accepted them. The practical application of the experimental method had transformed society. In medicine no noteworthy progress was made so long as knowledge was limited to the results of the observation of sick people. The beginnings of experimental medicine were extremely difficult. This method began to be applied to medicine about 1850. According to Osler, experimental physiology had done more for medicine than all the work of physicians from the time of Hippocrates to that of Jenner. The discovery of the relation of microorganisms to disease, which was one of the greatest steps in advance, was the result of the experimental method. Dr. Cannon related Pasteur's early experiments with sour wine and later with silk worms which had laid the foundations for the science of bacteriology, and called to mind that Koch's discovery of the tubercle bacillus was affected through animal experimentation. Our present campaign against tuberculosis would never have been possible without the experiments on animals. Trudean demonstrated the benefits of diet and fresh air in tuberculosis by animal experimentation. That tuberculosis was not inherited, was communicable, and therefore preventable, were facts demonstrated by animal experimentation. As a result of this knowledge the death rate from tuberculosis in Boston had fallen from 42 to less than 18 per 10,000 population. This decline in the death rate from tuberculosis had been noted throughout the entire civilized world. Dr. Cannon dwelt on the horrors of the bubonic plague and depicted scenes in London during the epidemic of 1665; then people sought to ward off the plague with charms, incantations, and resorted to astrologists. In 1894 the germ of the bubonic plague was discovered, and it was shown that the disease was spread by fleas among rats and when rats were not available these fleas preyed upon man. Now, instead of resorting to astrology, they used rat traps. To rats, guinea pigs, and monkeys we were indebted for this deliverance. The speaker next proceeded to describe the experiments of Loeffler which led to our understanding of the mechanism of immunity, and as a result we now had an antitoxin for diphtheria. Dr. Park had shown that in 1895 in 19 large cities of the United States the death rate from diphtheria was 80 per 100,000 population; in 1907 it was 17 per 100,000. Recently in Boston in 431 cases treated with antitoxin on the first day there was not a single death. Dr. Cannon quoted from a description of this disease written in 1870, which showed the harrowing distress of little children stricken with diphtheria and the helplessness and hopelessness of the physician in its presence. He then described cerebrospinal meningitis, 75 per cent. of the victims of which died and the remainder were left hopelessly blind, deaf, paralyzed, or imbecile. Dr. Flexner's experiments on monkeys had made possible the reduction of the death rate to 25 per cent., had shortened the duration of the disease, and had prevented the frightful after effects. This was one of America's cleverest contributions to the betterment of man's estate. The speaker then went on to consider the awful mortality from blood poisoning and gangrene before the time of Lister. The consequences of Lister's work were beyond calculation. Holmes had guessed that childbirth fever was contagious, but it remained for animal experimentation to prove it. Maternity hospitals were formerly regarded as portals of death; in one of the Paris hospitals the death rate was 57 per cent. There were puerperal epidemics that were to women what war was to man, and, like war, took the best and fittest members of society. Pasteur showed us the streptococcus and now the mortality from this infection was one-tenth of one per cent. This

was the result of animal experimentation. The whole science of drug action had been discovered by animal experimentation. Ergot was tested on animals before it was put on the market, and this seemed more fitting than that it should be tested on a woman who was bleeding to death. Antivivisectionists might think this over and take their choice. The Wassermann test for syphilis and Ehrlich's triumph were the result of animal experimentation. Animals were useful in making a diagnosis in some conditions, and in detecting typhoid and cholera carriers. If they were to prevent epidemics it was important to find these carriers, and without animal experimentation sanatoriums would be deprived of their weapons of defense. For their knowledge of physiological phenomena, vascular, cardiac, digestive, and the intricacies of the nervous system they were indebted to animals. A striking example of the value of physiological study was its revelations that had made possible the cure of cretinism. All these things showed an immense saving of human life, but the animals had shared in this benefit as well as mankind. Rabies could now be controlled and some diseases of animals had been entirely done away with owing to the fact that animals were more easily controlled and quarantined than man. Yellow fever had prevented the building of the Panama Canal by the French, while modern sanitation had made this feat possible, and sanitation owed its achievement to animal experimentation. During the Spanish-American War 90 per cent. of the army in one camp had typhoid fever, while last summer among 18,000 men mobilized on the Texas frontier, where typhoid fever was prevalent, not a man had the disease. Such were the results of protective vaccination. Had antivivisectionists no knowledge of these facts that they thrust forth hostile opinions of men long dead or engaged in other professions? Their whole course was characterized by fraud, duplicity, and ignorance. Why was it immoral to use animals for experimental purposes when they were destroyed in so many other ways: for food, for their skins, for plumage, simply to get rid of an annoying surplus. If the destruction of animal life was immoral, why single out this one instance, animal experimentation, and pass by the others in many of which animals were killed in much less humane ways. The animal experimenter never justified the infliction of needless pain. This statement the British Royal Commission, which had investigated animal experimentation, had endorsed. Directors of laboratories exercised enlightened compassion, yet in spite of this fact each year saw mild restrictive measures presented to our legislators. They pretended merely to investigate, but experienced laboratory workers were excluded from these investigating committees and only antivivisectionists appointed. These bills were merely initial efforts, opening wedges, to take from our hands the most powerful weapon of medical progress. There were fifteen such societies in Great Britain and six in this country. There was still much work to be done: scarlet fever, measles, and cancer were unsolved problems. "Who shall say that experimental progress shall cease? The antivivisectionist pleads for the animal that it may not suffer pain; the scientist for humanity, that man may live. Society must determine which shall prevail."

SECTION ON MEDICINE.

DR HENRY L. ELSNER OF SYRACUSE IN THE CHAIR.

First Day—Tuesday, April 16.

A Clinical Study of Relapses in Typhoid Fever.—Dr. HERMAN F. L. ZIEGEL of New York showed a chart of 21 relapses in typhoid fever which had occurred in a series of 168 cases. The condition was first recognized by Shultz and the speaker passed around a copy of the original monograph. As early as 1830 the pathology was shown to differ from that of other conditions. Relapses, he said, might be attributed to (1) a reinfection; (2) a difference of strains of typhoid bacilli in the system or the persistence of the organisms in the gall-bladder, or (3) the carrying of the scab of an old ulcer to another part of the intestine. Relapses were not due to hospital infection, because since hospital preventive measures had been instituted relapses were not less frequent than previously. The author defined a relapse as a characteristic repetition with a regular evolution of the cardinal signs of typhoid fever after defervescence of the original attack. A recrudescence was defined as the condition when the temperature had been low and then rose with increased severity of symptoms. The relapses were either mild or severe. Frequency was 26 per cent. and the ages varied between 16 and 56 years. Children were more predisposed. The onset came on after 4 to 5 days of apyrexia and freedom from symptoms during the convalescence from typhoid. There was a persistence in these cases of tumefaction of the spleen even after the apyrexia in 8 cases. No prodromi were noted, and there were no subjective symptoms the first few days. The symptoms were: a rise of temperature; enlarged spleen in 25 per cent.; roseola in 17 cases; leucopenia in 55 per cent.; a positive Widal, where it had been negative previously in 1 case, and a positive blood culture in 2 cases. The average duration of the relapse was 14.28 days, as compared to 22 days of the original attack. On account of partial immunity the attacks were mild. Temperature was intermittent. The diagnosis was made from the prolongation of temperature after a period of apyrexia; the reappearance of the roseola; the enlarged spleen, and the positive blood culture. Differentiation from typhoid sepsis; Brill's disease; typhoid pyelitis, pneumonia, and a recrudescence had to be made. The mortality was nil, complications were rare. The treatment in the future, the writer suggested, was to be the use of typhoid vaccines as a prophylactic measure to prevent relapses. The results were to be compared with those of cases not so treated.

Congestion of the Liver.—Dr. BENJAMIN W. STEARNS of Unadilla said the function of the liver was to safeguard the body by modifying the digestive products before entering the circulation. He quoted Moore, who said that it was the great metabolic laboratory of the body. Hemoglobin was broken up into pigments and the carbohydrates were modified for use in the body. In addition there were other unknown functions. The blood from the intestines to the liver was diluted with blood from the spleen. Nearly one-fifth of all cases seen by the general practitioners were due to the liver, and of these about one-third were being recognized. The symptoms of liver congestion were headaches, constipation, coated tongue, interrupted sleep, poor appetite, chilly spells, with diarrhea. The symptoms were relieved by cathartics and gastrointestinal treatment for short periods, only to recur in a few weeks. The physical signs were those of an enlarged liver. He mentioned that by placing the closed fist in the ninth or tenth intercostal space in the mammary line on the right side, by pushing in one inch and then giving a short punch, in congestion of the liver, an increased resistance could be noted. This condition, as a rule, existed in his cases for from a few months to two or three years. Jaundice was rare. Congestion of the liver was frequently the cause of parenchymatous nephritis. The treatment was calomel, gr. ¼, every fourth day and the administration of small doses of tincture of iodine and camphor by mouth. This produced regular bowel evacuation and a cure.

Vaccine Therapy in Medicine.—Dr. T. WOOD CLARKE of Utica said that practically all the known and many of the unknown infectious diseases were being treated by means of vaccines. He stated that vaccines were more beneficial in chronic infections than in acute ones. They were not indicated in acute processes like sepsis or pneumonia, but in chronic ones like acne and furunculosis. They might even do harm in short acute diseases. Vaccines were supposed to act in from five to seven days. In acute conditions, during the early stage the body, as a rule, was being overburdened in the effort to create immunity, and the administration during this negative phase might cause harm and perhaps death. The value of vaccines had been proved in typhoid fever prophylaxis. In the British and American armies they had proved very efficacious. To prevent relapses and complications they had been shown to be of inestimable value as well as in curing typhoid carriers. During the acute stage the benefit was questionable. In pyelitis, cystitis, and bacilluria due to the *Bacillus coli communis* doses of from 200 to 1000 million of autogenous and stock vaccines had been used with marked benefit. In genitourinary tuberculosis, where the distress was due to a secondary colon infection, tuberculin and colon vaccine gave great relief to the symptoms. Furunculosis was the ideal disease for treatment by vaccines, as it complied with the indications, being chronic, a local infection, and its pus easy of access for the manufacture of an autogenous product. Injections of from 50 to 600 million at intervals of from five to seven days should be given. In acne the *Bacillus acne* and staphylococcus vaccine were to be recommended. After the first injection there was noted an increase in the number of lesions and increased inflammatory reaction in those that existed. Those disappeared and the disease was cured in from three to ten injections. Other skin diseases had also been cured with vaccines, such as eczema, erythema multiforme, etc. The efficacy of streptococcus vaccines in septicemia and erysipelas in the author's experience was very doubtful. In vulvovaginitis he succeeded in curing the cases in about 1.7 months, as compared to 10 months in cases treated

by other means. In Riggs' disease good results were obtained by making a vaccine from the pus of the sockets of the teeth. In conclusion, he stated, the patients must be selected cases; the vaccines should be autogenous. He recommended the use of small doses to begin with. The patient should be watched for reaction symptoms. The physician should be familiar with the indications and contraindications and the symptoms of a reaction.

Graphic Methods in the Diagnosis of Heart Lesion.—Dr. LEO H. NEUMAN of Albany demonstrated the polygraph and made a plea for the use of the instrument by the general practitioner. He mentioned the advantage of using an arm band instead of taking tracings from the radial artery, as the artery moved from side to side and the resulting tracing was untrue. He then demonstrated the various curves in charts.

The Signs of Overdosage in Digitalis Administration.—Dr. WALTER A. BASTEDO of New York said that poisoning from digitalis almost always occurred from therapeutic use of the drug. In a recent study of ninety cases at the Bellevue Hospital 25 per cent. showed some toxic manifestations of the drug. Some of these manifestations might be due to other causes. The toxic symptoms of digitalis might appear two or three days after the administration and disappear in the same manner. The subjective symptoms were (*a*) loss of appetite; (*b*) oppression about the heart, palpitations; tachycardia and consciousness of skipped or premature beats; and (*c*) headache. The objective signs depended on the manner of examination, and the electrocardiogram showed the following parts of the heart to be affected: *a*, the sinus node, with either alternation in rate of beat with slowing and acceleration, sinus arrhythemia; *b*, the auriculoventricular bundle with partial or very rarely complete heart block; *c*, the ventricular muscle with excitability, an early indication of toxicity, with the production of extrasystole, occurring frequently, and *d*, all three might be combined and evidenced by coupled rhythm, phassic arrhythmia or pulsus alternans. The coronary artery might be affected and the pulsus alternans might perhaps be caused, in the author's opinion, by a deficiency in the cardiac nutrition due to the spasmodic action of digitalis on the blood-vessel.

The Physical Treatment of Arterial Hypertension.—Dr. EDWARD C. TITUS of New York opened this subject by remarking that the cause of the hypertension must always be first ascertained, and the physician should not be contented with a diagnosis of arteriosclerosis. In the treatment of hypertension he said the diet must be modified according to the individual and according to the condition of the kidneys. The amount of food was to be reduced, as well as the proteids. A liberal milk, buttermilk, and vegetable diet was advocated. Alcohol, tobacco, tea, and coffee should not be interdicted. Many women were overfed and underexercised. The amount of exercise should be gauged by the blood pressure. Hydrotherapy was to be guided by the general condition of the patient. Cold baths were not recommended. Prolonged warm immersions, followed by showers and a rub down, seemed rational to the speaker. Massage was recommended when the patient was unwilling to take exercises. Electricity in the form of autocondensation was recommended in daily treatments of from twelve to fifteen minutes with the patient on a couch and when the blood pressure lowered at great intervals. He said that this treatment relaxed the vascular spasm of the peripheral vessels, increased the perspiration and amount of urine excreted; caused increased oxidation and hastened elimination and stimulated cell metabolism, as shown by the well-being of the patient. The pulse became softer and more regular, and there seemed to be a general improvement in the circulatory system.

Hydrotherapy and Mechanotherapy of Arteriosclerosis.—Dr. JOHN M. SWAN of Rochester defined arteriosclerosis as a progressive degeneration of the vascular system characterized pathologically by thickening of the walls of the blood vessels and clinically by an increase in blood pressure. The pathology might vary from a slight internal thickening to atheroma. The symptoms were, as a rule, variable, and referred to the heart, brain, kidneys, and skin, and often resembled neurasthenia. The treatment with drugs was unsatisfactory. Recently physiological methods had been instituted by means of rest, massage, hydrotherapy (various baths) and electricity. He mentioned one case where by means of rest in bed for two weeks he reduced the blood pressure of a patient sixty-eight years old from 170 mm. mercury to 140 mm. within two weeks, and in the same patient with baths alone the blood pressure only went down 10 mm. The Nauheim baths he strongly condemned, and said they were harmful. He recommended the Russian vapor or neutral full immersion baths. Autocondensation electrical treatment he had tried, and one patient after several daily twenty-minute treatments developed an attack of acute cardiac dilatation with an increase in blood pressure. As a rule, however, the blood pressure of patients so treated was somewhat lowered. In other cases it remained the same or was slightly lowered. His conclusions were that rest in bed with massage were beneficial when done daily, that the total amount of food should be limited, and the measures that tended to produce sweating—as baths, vapor and neutral full baths, either salt or fresh—were indicated. The faradic, galvanic and high frequency currents relieved the sensory skin disturbances when used judiciously.

Dr. LOUIS F. BISHOP of New York said that Dr. Bastedo did not use the term physiological instead of toxic in speaking of digitalis. The toxic symptoms of digitalis might be preferred to the symptoms of cardiac insufficiency in a few cases. Mackenzie recommended, he said, the administration of the digitalis until toxic symptoms appeared. It was much safer than supposed. Autocondensation, he remarked, killed many people who had no business to use it.

Dr. BASTEDO remarked that digitalis was a very safe drug if stopped when effects of cumulative action were noticed, but the symptoms might come on some time after use.

Dr. TITUS said he had never seen ill effects from autocondensation when properly used. One should not use cheap apparatus, and ill effects were due to a poor case or overdosage.

Dr. SWAN said we were too prone to pay attention to the sphygmomanometer and not enough to the patient clinically. In order to get the best results both were to be considered together.

Hyperacidity.—Dr. GEORGE R. LOCKWOOD of New York said that hyperacidity was an abnormal increase of hydrochloric acid in the stomach during the digestive period, and that during the fasting period the stomach was empty. In hypersecretion there was present a large amount of gastric juice in the fasting condition. Hyperacidity must always be considered a symptom. It was present in his series cases in 13.8 per cent. It was always thought that dietetic errors were an etiological factor, but he could not find it so. Those individuals with narrow costal angles were susceptible as well as those with enteroptotic predispositions. Of his cases of hyperacidity 22.5 per cent. were in gastroptosis; 19 per cent. in ulcer of the stomach or duodenum; 9.5 per cent. in chronic appendicitis; 11 per cent. in gastric atony; 5.5 per cent. in gall-bladder disease; 5.5 per cent. in chronic gastritis; 4 per cent. in cancer. The remainder, about 20 per cent., were functional or undiagnosed. In 80 per cent. there was some organic cause. All had motor atony in common. Of 233 cases of gastroptosis 27 per cent. showed hyperacidity. The greater the degree of muscular error the greater was the acidity. In ulcer the pyloric obstruction was a factor as in cancer; 30 per cent. of all gall-bladder cases had hyperacidity, and these may have been due to pylorospasm, as shown by Moynihan. In most cases hyperacidity meant a latent course.

The Significance of an Acid Gastric Juice in the Fasting Stomach.—Dr. HAROLD BARCLAY of New York read a paper based on 1700 examinations of gastric juice. The normal stomach emptied itself in from 5 to 7½ hours after a meal. The presence of 5 to 30 c.c. of fluid was supposed to constitute a hypersecretion. Those that contained food particles after 10 hours did not belong to this class. In fifty-five cases of hypersecretion the volume obtained varied from 50 to 130 c.c. of clean, straw-colored fluid, in which there was no starch. These examinations were repeated time after time. This condition was found in a variety of conditions, including salpingitis, prostatitis, cancer of the rectum, and the diseases mentioned in Dr. Lockwood's paper. Over 60 per cent. were in neurasthenics. The motor error alone was not responsible. Symptoms were not always due to a definite lesion in the gastroenteric tract. Many were reflex.

Dr. DASH of New York emphasized the fact that he could not diagnose gastroenteric lesions without functional estimations. The nervous manifestation could be caused by an excessive activity of the stomach due to reflex stimulation. Patients ought to be given double tests, one on fasting and the other after a test meal. This would give an idea of the relative function. There were not to be found any organic changes in the glands of the stomach during hyperacidity. This might also be found in tabes and early in carcinoma.

Dr. NEUMAN of Albany said hyperacidity might be dependent on many causes. He said we must recognize a physical basis for reflex conditions. A spasm in the pylorus would produce stagnation of food in the stomach, and nature's attempt to be rid of this food was by in-

creased acidity. This again was followed by hypoacidity.

Dr. Stockton of Buffalo said there was a tendency to localize the disease in the mucosa, pylorus, gall-bladder, and appendix, but the nervous system should be considered.

Second Day—Wednesday, April 17

Toxemia of Pregnancy: A Consideration of Treatment.—Dr. Wm. M. Brown of Rochester divided the subject into the prophylactic and curative treatment. He said the individual manifestations of the condition and the case treated should be studied. Because of the lack of knowledge there existed many theories as to the origin of the toxic substances. For this reason scientific prophylaxis was not easy. The pathology was shown by a marked protoplasmic degeneration in the liver, kidney, heart, and brain. Therefore, he recommended the establishment of a well balanced elimination of metabolic products with the least possible cell energy. The presence of a large ammonia coefficient and acetone in the urine was to be ascribed to cell destruction. Therefore tissue energy must be conserved and the patient fed up. There was usually present an increase in the sodium chloride and a decrease in the calcium salts. To illustrate the use of lime salts he cited the following case: A primipara was admitted to the hospital with marked vomiting and albumin in the urine. Proctoclysis by the slow method was given. In twenty-four hours she voided sixteen ounces of urine containing a large amount of albumin and acetone. Nutritive enemata were added, and the vomiting still continued. Then 30 grains of calcium lactate were administered in the enemata. She had vomited once since that time and had continued her pregnancy without trouble, being put on a regular diet. In severe cases with symptoms of central origin as hypertension, coma, and convulsions, watching the circulation had been of great value. Administration of magnesium sulphate, hot packs, venesection and intravenous infusion of saline or cane sugar solution were highly recommended. Veratrum viride might be dangerous, as he considered it as adding another poison to the toxins present in the body. Vigorous elimination by the use of active cathartics should be begun early and delivery should not be hastened. That was to be considered the last resort.

Dr. Walter B. Chase of Brooklyn said the question was whether to save the patient or not, and what means should be used. Delivery ought not to be hastened. To the cathartics mentioned he added elaterin and croton oil as valuable adjuncts. The amount of fluid lost in this way was to be replenished as soon as possible.

The Results of the Early Diagnosis of Urinary Tuberculosis.—Dr. Wm. F. Braasch of Rochester, Minn., read this paper. He said that most cases of renal tuberculosis came to operation when the process was already well advanced, and that of all cases seen only 10 per cent. came during the first six months of symptoms. This was due to the fact that the true nature of the disease was unrecognized, that it was not generally known that surgery was the best means of treatment and that there existed a widespread belief in other cures. Regarding the early diagnosis, he said any case with diurnal bladder irritability with pyuria lasting over a period of several months should be considered tuberculous until otherwise proven. In many cases the irritability might be neurotic, but usually it was then not nocturnal and not attended with pyuria. The usual diagnosis made was Bright's disease, on account of the presence of albumin; because pus was not looked for. A careful examination of the urine should be made. If no pus was to be found tuberculosis could be excluded. With pus present, the diagnosis was to be established either by the presence of the tubercle bacillus or by guinea pig inoculation. This, he said, occurred in every early case. The physical examination in some cases revealed an important sign, a thickened epididymis. Thickening of the ureter and enlargement of the kidney were late signs. By cystoscopy, the localization of the process and degree of bladder involvement were to be made out; whether the infection was ascending or descending; which kidney was involved; whether both kidneys were diseased and the functional capacity of the organs. In the writer's opinion the use of tuberculin was valueless. The cure of renal tuberculosis without surgery was exceptional. The mortality during the last ten years at the Mayo clinic from nephrectomy was 29 per cent. Complications outside the genitourinary tract did not necessarily contraindicate operation. Marked involvement of the prostate rendered the prognosis less favorable.

Dr. Furniss of New York emphasized the importance of an early diagnosis. His experience was mostly with female patients. He said one might get pyuria in young women with irritability of the bladder. In neuroses or chronic urethritis the diurnal irritation was greater than the nocturnal. Hemorrhage was an early sign in this disease. Cystoscopy showed both ureter openings apparently normal until late in the disease. In women it might be possible to palpate the ureters per vagina. In young women bladder irritability usually meant tuberculosis.

Relative Value of Air, Food, and Rest in the Treatment of Pulmonary Tuberculosis.—Dr. Lawrason Brown of Saranac Lake gave a summary of the recent advances in the treatment of tuberculosis. He said fresh air was used in other diseases besides tuberculosis. Coolness, dryness, and active motion of air were essential factors. The temperature in good health resorts should have a daily variation of about 20 degrees and he gave as an example the climate of Arizona. In 1200 patients at Saranac Lake the maximum weight increase took place from August to December. Very prolonged or very intense cold was too exciting to the patient. On the dryness of the air depended the amount of moisture that was absorbed from the body. He recommended the use of the roof rather than the window tent, as there were less bacteria present, the air was cooler, dryer, and in motion. Regarding diet, he quoted: "Eat once for yourself, once for weight, and then once for the bacteria." The scales, he said, were the best criteria of diet, in a patient with no temperature or complications. The aim was to bring the patient slightly above his normal weight, by gaining one pound per week. Then the diet was to be reduced to the lowest point of table comfort and not enough to cause any loss in weight. Milk should be cut out, and three meals given, with plenty of carbohydrates. Digestive disorders must be treated. Rest was imperative, with the author, in treating these cases, even when no temperature was present, and in his opinion autoinoculation by means of exercise was injurious, and fraught with great peril. Rest of lungs could only be obtained with the patient in bed. It oftentimes relieved the cough. The energies were to be used in combating the disease. Boating and driving could gradually be carried on, with the patient in bed afterward. The exercises were fitted at the sanatorium to the various callings of the patients.

Dr. Henry B. Doust of Syracuse said that rest was the cornerstone in the treatment of febrile cases. The physician, he remarked, always thought first of the fresh air and food. The emphasis was to be placed on rest. He believed in rest until the lesion in the lung became inactive, and said that exercise killed many patients. Superalimentation was to be carried on only until the patient was brought up to weight.

Dr. Solomon Solis-Cohen of Philadelphia said the paper represented a decided advance in the sanatorium treatment of tuberculosis. Treatment by rest alone or food alone was injudicious. Both were to be combined.

Dr. Brown, in closing, said that by rest he meant a combination of rest in bed and the work the patient was fitted for. He said tuberculosis was never cured, the process was only arrested, as no one could tell when the tubercle bacillus was killed, but the patient was to be benefited by rest and work. The pulse, he said, was a good indication of the amount of work the particular patient could stand.

The Treatment of Typhoid Carriers.—Dr. Frederick M. Meader of Syracuse said that it was a difficult matter to detect and treat typhoid carriers. The treatment he recommended was by immunization. He explained the usual processes of immunity, mentioning the presence of complement in the blood and the manufacture of amboceptors. The latter, he said, could be increased by injecting a vaccine of typhoid bacilli, in which the organism's vitality was partially impaired, but not totally destroyed. It was better in some instances to use a stock vaccine rather than an autogenous one, as the organism might have become immune to that particular host's antibodies. He reported a carrier in which he had given several injections of vaccine, where typhoid bacilli were found in the stools. As the dosage increased, the amboceptor content in the blood became greater and the bacteria disappeared from the stools. A similar case gave a like result, but he could not say that it was a cure, as she had cleared up spontaneously before. A third case, he said, was under treatment at the present time. This one also showed a gradually increasing amboceptor curve. His conclusions were that (1) frequent administration of vaccine did not rush antibody production; (2) comparatively large doses were needed; and (3) recent work indicated that stock were better than autogenous vaccines for this purpose.

Dr. Charles F. Bolduan of New York said that 3 to 5 per cent. of all typhoid patients became carriers, giving New York State 20 to 30 yearly. The discharge of bacilli as a rule was intermittent. He said the most logical treatment was the one above described and should be tried.

Dr. Edward C. Rosenow of Chicago mentioned a case of a woman with a fibroid who had an attack of typhoid with marked anæmia and sepsis, with two recurrences of the fever. He thought perhaps the fibroid might have harbored some of the typhoid organisms. He said bacterial immunity was the main means by which to get rid of the typhoid organism.

Dr. Abraham Jacobi of New York said that we ought to begin at the beginning. We should get rid of typhoid fever by supplying pure water and pure milk.

Nonsurgical Treatment of Exophthalmic Goiter.—Dr. Solomon Solis-Cohen, of Philadelphia, remarked that the medicinal and surgical treatment of Graves' syndrome were good in their places. The disease was not always due to hyperthyroidism. Many cases had been described by the author with all the symptoms but no goiter, and these cases recovered without surgery. He hesitated in reporting them because he thought some were spontaneous cures. The enlarged thyroid gland was a secondary factor with additional symptoms working in a vicious circle. The first factor in medicinal treatment to be considered was an early diagnosis. Then individualization of the cases was commented upon by the author, as one line of treatment might be of benefit to one case and not to another. Under this head, heredity and tuberculosis, 6 were considered as important factors. By recovery the author meant a disappearance of the symptoms, although the enlarged gland might have remained. He believed that spontaneous recoveries took place in many cases. Rest was the greatest factor in the treatment. The diet was to be carefully regulated not to overtax the system with proteids and carbohydrates. Open air was advocated. Enteric intoxication was to be corrected by flushing and with drugs such as calomel, naphthol, guaiacol, etc., to produce partial intestinal antisepsis. Systematic application of hot and cold by means of electricity or water in order to bring up the vasomotor tone of the patient was of benefit. In order to obtain success with organic extracts, their reliability must be ascertained. The best results were obtained with fresh extracts injected hypodermically or with the gland eaten fresh. The posterior lobe of the pituitary gland, the thymus or reliable preparations of the adrenal glands might be used. The parathyroid might prove a valuable adjunct in controlling the tremor, which might be due to pathological or mechanical involvement of the gland. Drugs, he said, were all symptomatic reliefs. Much benefit had been obtained by the use of neutral hypobromide of quinine. Cactus with rest and strophanthus or digitalis had been found to steady the blood pressure. It had no effect upon the heart unless the rhythm and tone were disturbed. Application of iodine as an ointment locally to the gland in some cases promoted absorption, where the enlarged gland was one of the early symptoms. Electricity had proved useful in the author's hands, in the form of a high frequency current, during the past three years. He said that now there was no specific treatment for this disease. Beebe's serum was of value in some cases. Thyroidectin and autothyroidectin were valueless. The points of importance were, early diagnosis, individualization of cases, rest, and the medicinal adjuncts.

Dr. Eliza Mosher of Brooklyn reported a case illustrating the difficulty in diagnosis, where the onset was with cardiac symptoms. The case was entirely cured by rest.

Dr. George Stockton of Buffalo said the cases must be worked out individually. He was glad that Dr. Cohen has spoken well of cactus and strophanthin.

Dr. Joseph Collins of New York remarked that we should be able to distinguish between the various types of cases for treatment. Otherwise the treatment had to be empirical. Rest gave the best results, together with a purin-free diet. Electricity was of no avail.

Dr. Henry Elsner of Syracuse said the disease was a self-limited one, and that the patients cured themselves. The thyroid gland in its hyperactive state wore itself out during hyperthyroidism and finally this was followed by a condition of myxedema. He thought it dangerous to prescribe organic extracts without specific instructions. He also mentioned that he had frequently noticed the association of goiter with fibroid, especially of the uterus.

Dr. Cohen, in closing, remarked that disappointment from the use of cactus was due to the fact that one did not know what preparation he got. He thought regarding the theory that the reciprocal actions of the hormones lay at the bottom of the etiology of exophthalmic goiter. Hyperthyroidism was, he said, a late symptom. He remarked that Dr. Collins was correct in the statement that spontaneous recovery takes place in a certain percentage of cases, but some were left open for discussion. He repeated that electricity was a valuable aid in very many cases. He also noted the presence of fibroids as well as petechiæ, and papillary excrescences in exophthalmic goitre. He also said that in many cases the thyroid gland finally atrophied and thyroid extract must be administered.

Reciprocal Relations of Cardiac and Hepatic Disease.—Dr. Alfred Stengel of Philadelphia said that the liver was a very elastic organ, which varied in size with changes in the circulation. It distended very markedly under saline infusion, and by experiment it had been shown that it would accommodate 100 per cent its original volume of blood. The changes in cardiac disease were of three types: (1) passive congestion or nutmeg liver; (2) cholangitis, and (3) fibroid perihepatitis. In the first condition, when the heart failed the liver swelled, and vice versa. At times the large liver had been mistaken for tumor formation, because there was as yet no evidence of failing cardiac compensation. However, it was to be interpreted as a conservative effect, for in this way the liver acted as a buffer, when the heart was being overtaxed. On frequent repetition, these cells became degenerated near the central veins and on the periphery a fatty change occurred, and a nutmeg liver was the result. This capacity of this type of liver was only 0.6 per cent. additional. Fibroid changes in secondary cardiac cirrhosis of the liver then followed, further impairing the elasticity to .45 per cent. capacity reserve. He illustrated this condition by reporting a case under treatment for six years, where the first sign of a failing compensation was given by pain in the right side. This was followed by ascites, enlargement of the spleen and fully developed cardiac cirrhosis. In the early stages the liver acted as a reservoir of the blood for the heart, in the end it acted the reverse and made the heart act with difficulty. Jaundice of the severer grades was not to be interpreted as a cirrhosis, as it occurred but rarely. Perihepatitis, also known as Pick's disease, occurred with cardiac affections. Toxemia, due to impaired liver function, affected the heart and caused in some instances degeneration. Pent up infection in the gall-bladder by toxemia and reflex irritation of the vagus might cause cardiac manifestations. In the writer's belief the above facts pointed to active treatment to unload the liver when affected by indiscretions in diet, and to regulate the latter.

Clinical Vagaries in Certain Forms of Liver Disease.—Dr. Nathan E. Brill reported two interesting cases. A young man aged 18 years gave gastric symptoms of pain and vomiting for 3½ years. He was admitted to the Lebanon Hospital and a diagnosis of ulcer of the duodenum or stomach was made. Exploratory laparotomy disclosed no abnormality. The appendix was removed. Two months later the symptoms returned. For six weeks he had had chills, fever and jaundice. Was admitted to speaker's service at Mt. Sinai Hospital, where he developed pain radiating to the right shoulder. Physical examination revealed only an enlarged liver. Test meal was negative. The liver became larger and he became so anemic that his hemoglobin fell to 11 per cent. He was transfused with benefit to his anemia. Analysis of food from a duodenal bucket showed an absence of pancreatic ferments. Three possibilities were thought of: (1) postoperative adhesions; (2) tumor, and (3) Hanot's cirrhosis. Operation disclosed fluid in the abdomen. The liver was olive green in color and very much wrinkled. On puncturing it a few drops of gelatinous fluid escaped from the parenchyma. An autopsy finally revealed the true condition, when an annular sarcoma was found to involve the duodenum, completely obstructing the pancreatic and bile ducts. The second case was that of a man whose liver enlarged daily, without ascites, the liver extending to the ilium. Dr. Brill thought this was probably a case of hyperplastic cirrhosis of the liver, with an increase in the number of cells and in the intercellular fibrillar connective tissue.

Further Studies in Endocarditis.—Dr. Edward C. Rosenow of Chicago, Ill., said that Osler first called attention to the chronic septic or what was now called malignant endocarditis. He said this disease began insidiously, with no history of previous infection, with little or no fever. The cases ultimately, however, became septic and ended fatally. These were now clinically recognized. He said this disease was due to an organism variously termed the *Streptococcus viridans, Streptococcus attenuans* or saprophytic streptococcus. It was to be found in other conditions quite commonly. He believed that this organism was a modified pneumococcus perhaps originating from the tonsil, where it was normally present. He said its properties were: it grew green in blood agar, adhered tightly to the surface, and grew in clumps in the liquid media. In rabbits it had produced endocarditis, affecting principally the valves and chordæ tendineæ. Out of 25 attempts he succeeded in 18, by intravenous inoculation. It was nonvirulent to animals in the ordinary sense of the term,

yet it is said to kill almost every patient that it infected. It usually was found to occur in a previously diseased and vascularized valve. He demonstrated specimens of rabbit's hearts showing lesions varying from hemorrhages to vegetations produced by the intravenous injection of this organism. He believed that these infections were embolic in origin. During the final course of the disease, however, they might have a mural implantation. He spoke in detail of one protracted case where he isolated the organism on almost every attempt and he tried 50 or 57 times. He observed these facts in the case. When the temperature was low the number of colonies per ccm. of blood was high, and when the temperature was high the opposite was true. At the same time when the temperature was low, the bacteriolytic power of the blood was increased, and the phagocytic power was normal. This indicated to him immunity of the bacteria to the host's immune bodies, and he said that was the reason why these patients as a rule could not be cured. Vaccines as tried by him simply did harm, as evidenced by chills and an increased number of bacteria in the blood cultures. The chills meant that the patient had succeeded in destroying a large quantity of organisms and had liberated a large amount of toxic material.

Dr. LIBMAN of New York said that, compared to human lesions in the endocardium, those of the rabbit were somewhat drier. He emphasized the frequency of this type of endocarditis. He said it was a great deal more frequent than was thought. Regarding the causative organism he remarked it never caused hemolysis in the blood plate until 48 hours later. In some, capsules had been demonstrated. He did not believe it should be called the pneumococcus and suggested the name *Parapneumococcus viridans*, as being a diagnostic one to the general physician. There was no real treatment to advise. He said he had collected evidence from ten cases that this disease can heal itself quite often. Old, typical lesions of this type of endocarditis had been seen by him post-mortem. Those that gave positive blood cultures usually died. He mentioned a few cases in the literature reported as recovered.

Dr. BROCKETT of Oneida reported one case of endocarditis following scarlet fever, in which he found an organism corresponding in its characteristics to the coccus described.

Dr. ALEXANDER LAMBERT of New York agreed with Dr. Libman that this disease was very frequent. He said since his connection with Bellevue Hospital he had seen many such cases, but in them no positive blood culture was obtained. Many of these patients died without the organism having been found in the blood.

Dr. HENRY ELSNER of New York said he had seen 7 cases of this type of endocarditis within the last three months. Dr. Rosenow was right in his statement that these infections were always engrafted on a previous endocarditis. These cases were not all easy of diagnosis. He said they often simulated typhoid fever, as there might be no evidence at first of local endocardial change, which might appear only suddenly. A valuable sign, he said, was terminal hemorrhagic infarction. A negative blood culture meant nothing, a positive one, everything. With a chronic type of fever, with or without chills, a characteristic blood count, petechiæ, enlarged spleen and evidences of infarct, with no other cause for the symptoms, a suspicion of the above condition should be borne in mind. He had not seen a case of recovery.

Dr. ROSENOW in closing said when a patient came to him with cardiac trouble, he always advised total removal of the tonsils, as a prophylactic measure. The organism, he said, could be missed in two ways technically. Agar plates should always be made and not too little or too much blood must be added to the fluid media. In the former the growth was found to be practically nil and in the latter it was so enmeshed in the fibrin, clumped together that it could not be seen. The proper balance in the mixture must be obtained. He obtained positive cultures in every case that ended fatally, and of 4 cases in which the cultures were negative recovery occurred in all. Regarding the name of the organism he said that was unimportant. The importance lay in finding it. It should certainly *not* be named *Streptococcus endocarditidis*.

SECTION ON SURGERY.

THE CHAIRMAN, DR. PARKER SYMS OF NEW YORK, IN THE CHAIR.

First Day—Tuesday, April 16.

Surgery of the Battle Field.—Surgeon General GEORGE H. TORNEY read this paper by invitation. He said that within fifty years there had been a radical reorganization of armies. Weapons had changed, and this necessitated a change in the surgical methods of the army. The system used on the battlefield consisted of three divisions—collecting, dressing and distributing. In war, sentiment and even humanitarian feeling had to give way to success in battle. Wars in the future would consist in a quick succession of battles, thus enormously increasing the number of wounded that had to be cared for within a short time. There was never a sufficient personnel in the medical department of an army, no matter how well organized. Because of the long range of rifle fire in modern firearms the danger of surgical service of the army was vastly augmented. The danger in the rear was almost as great as in the front. Their first aid and dressing stations were within rifle range. In spite of this a comparison of the number of wounded in several battles of the Civil War with those of the Russo-Japanese war showed that the number of wounded was not much greater now than during the time of the Civil War. In the future, surgery on the battlefield would have to be limited to emergency cases. The speaker described the work of handling the great number of wounded. In one instance 1,200 men were given surgical attention during one afternoon and evening. Neither did the work of the military surgeon cease with the campaign. During the Civil War 97,000 men died in battle, while 164,000 died of epidemics and sickness. This condition was now changed. Lantern slide pictures were shown illustrating the work on the battlefield.

Surgical Treatment of Old Dislocations of the Shoulder and Elbow.—Dr. LUCIUS W. HOTCHKISS of New York read this paper. After relating the history of the operation of arthrotomy he said that these dislocations might be divided into two groups. First, those which were irreducible from their inception, and second, those which had become so through luxation and the formation of adhesions. In the first group the conditions which might prevent primary reduction were numerous. The head of the displaced radius might be thrust through an overlying muscle, or the head of the humerus might be restrained by an interposing tendon or muscle, or there might be a complicating fracture of the head or neck or process of the bone which rendered reduction impossible without resection. In the second group, which was the larger one, adhesions, contraction of the aperture in the torn capsule and contracting adhesions and atrophy of the muscles and soft parts secondary to trauma, together with other conditions, might make manipulation difficult and dangerous. In old people the closed method was extremely dangerous because of the danger of involving blood vessels, tendons or nerves. It was only by direct inspection that such an operation could be made safe and effective. The mortality in these operations by the open method was about two per cent., which was the same as for the closed method. The speaker had operated on 15 cases, eight of which were of the shoulder, and seven of the elbow, with no mortality. Some stiffness might be expected, but this was amply compensated for by the movable scapula, or restoration of the contour of the shoulder and freedom from pain. Arthrotomy consisted in incision into the affected joint for the purpose of determining on further procedure, and consisted in the division of adhesions, careful conservation of certain tendons, nerves and vascular trunks. Much depended, therefore, on the judgment of the surgeon. In his experience he had dealt only with anterior displacements of the shoulder. Operation on the elbow was more difficult; he used the anterolateral incision described by Kocher. He thought the method of Stimson, carefully followed, best enabled one to open the olecranon fossa, chisel off new growth of bone and deal with various constructing bands.

Dr. I. S. HAYNES of New York said that in attempting to reduce not too old dislocations of the elbow he extended the forearm, adducted it to bring the head of the radius down below the capitellum, then by abducting the forearm, the head of the radius acting as a fulcrum, the olecranon fossa was brought down over the capitellum. When it was necessary to excise the head of the humerus he made the line of section oblique so that the plane of section would look in the same direction that the head did.

Treatment of Simple Fractures by the Open Method.—Dr. JOHN B. WALKER of New York read this paper. He said that in no class of injuries was the prognosis so uncertain as in fractures. Surgeons had been neglecting this subject for abdominal surgery. In Pennsylvania there had been appointed by the State Society a committee to inquire into end results of fractures of the femur and the results had not been as satisfactory as was supposed. The time occupied in recovery was frequently unexpectedly long, especially in the recovery of function. The degree of function that had been secured could usually not be deter-

mmed until after the lapse of one year. He considered the open method applicable to fractures of the patella, olecranon, with wide separation of the fragments, in articular fractures with displacements of the head, fractures of the carpal scaphoid with displacement of the proximal fragment. Operations were indicated in these cases because the resulting disturbance of function was greater when the non-operative method was employed. Other types of articular fractures should be examined at the earliest moment under anesthesia, reduced, fixed and an *x*-ray picture taken, and then there should be careful deliberation before attempting operation. The operation might be said in a general way to be applicable to fractures of the upper and lower third portions of the long bones and on the joints. The question as to the advisability of employing the open method in these cases was propounded to a body of surgeons some years ago and 85 per cent. favored the open method; recently the same question was put to a similar body of surgeons and 85 per cent. favored the open method. Dr. Walker presented a number of slides comparing results obtained by the two methods and showing a number of cases in which the closed method had signally failed and which had been restored to a normal condition by operation.

Treatment of Simple Fractures by the Closed Method.—Dr. JAMES M. HITZROT of New York read this paper, in which he showed what could be done by the closed method in cases of fracture, provided the surgeon possessed sufficient skill and knowledge of mechanical forces. The closed method was less dangerous, as it avoided the danger of infection, and it was by no means as limited in its application as many seemed to believe. The reason results were unfavorable in so many cases was the patients were negligent or the surgeon did not possess sufficient knowledge and good judgment to deal properly with them. The earlier the fracture received attention the better were the results. If reduction was impossible, of course they had to resort to resection. The closed method was particularly applicable to Colles' fractures and Pott's fractures and to those of the forearm and lower leg. He thought there was nothing better than the moulded plaster splints used by Stimson. In robust and muscular individuals and in those of extreme age or those in whom for other reasons reduction could not be effected, some form of extension and fixation, permitting continuous traction, should be applied. This method by traction could not be properly carried out by men not capable of appreciating mechanical details. The degree of abduction and flexion was a problem for each case. Where immediate reduction was possible, and control palpation, measurement, and alignment of the limb as compared with the opposite side were satisfactory, fixation should be at once applied. The results of traction should be controlled by daily measurements, palpation, and adjustment of the alignment. It was folly to take off the weight and move the patient to take an x-ray picture after a week or ten days, as it would give little or no value as to the worth of the extension. Dr. Hitzrot exhibited a number of lantern slides showing how the extension apparatus was used and the perfect results that had been obtained in a number of cases.

Dr. SAMUEL LLOYD of New York said that in his opinion one should be prepared to treat these cases by either method. In cases where the displacement could be overcome completely and retained in apposition readily, when crepitus was clearly made out, no surgeon should think of operative measures. On the other hand, when it was evident that the fragments could not be held in position or when the fracture was complicated or multiple, especially where there were small fragments, he operated and put the fragments in position. In cases where crepitus could not be obtained it was evident that there was a shred of tissue or a blood clot separating the fragments. These cases must be operated upon. When complete reduction could not be obtained in fractures of the elbow operative treatment was absolutely essential. He referred to a paper which he had read before the society in which he showed that ankylosis of the elbow joint was nearly always due to bone deformity, either displacement of fragments or callous, and not to fibrous bands. He said he wished Dr. Walker had spoken of the treatment of fractures of the head of the femur by the open method. He believed that good results in fractures of this class could be obtained if the fragments were brought in apposition by plates or nails.

Dr. A. T. BRISTOW of Brooklyn said there were two objects to be attained in the treatment of fractures, the restoration of function and the prevention of visible deformity. It was quite possible for the *x*-ray to show considerable deformity when as a matter of fact little actually existed. It did not follow that because the *x*-ray plate showed a want of apposition one should resort to the open operation. An infection in an ordinary wound of the soft parts was rarely serious, but it was far different in a bone operation, because here one had to deal with an infected compound fracture, which was one of the most serious of conditions which confronted the surgeon.

Lateral Curvature of the Spine.— Dr. WALTER TRUSLOW of Brooklyn read this paper, in which he made a distinction between functional weak back and structural scoliosis. He said that in functional weak back they should hunt out some cause for the condition by examining with great care as to detail into the habits of life of the patient, into the clothing, nourishment and hours of study, etc. This condition was principally due to muscular weakness, and the treatment indicated was proper training as regarded posture, exercises of various kinds and muscle building, and the child that was not remedied by these hygienic measures should have mechanical support. The question for the physician to decide was whether the child could in the short time that could be given to treatment secure the training needed; if not, a brace should be applied. In structural deformities these measures fould be of no use; it was necessary to apply force to the deformity and then to maintain the corrected posture by means of a plaster of Paris jacket. The attention should be directed to pressure and traction on the thorax when the patient was in the extended position. In 1911 Abbott had obtained greater correction by applying the jacket in the flexed position (dorsal decubitus). The writer said he could not give any opinion as to the relative value of these methods. The benefit of the treatment depended upon progressive untwisting of the spine and upon the use of chest developing windows at the sites of thoracic depression.

Operations in Pott's Disease.—Dr. RUSSELL A. HIBBS of New York read this paper, in which he described his operation for Pott's disease, illustrating it by lantern slides. The operation had been performed in three cases one year ago, and at this time the results were excellent. Few cases, however, recovered with movable joints.

Dr. H. B. WHITBECK of New York called attention to the importance of early diagnosis in Pott's disease as in pulmonary tuberculosis. By early diagnosis and efficient treatment with a plaster jacket or brace, cure with little or no deformity could be obtained. He emphasized the importance of efficiently applied jackets or braces immobilizing the spine in the greater part of its extent.

Dr. CARLTON WALLACE of Syracuse said that Dr. Hibbs' operation was a good one if he could shorten the period of treatment to one year, when it usually took from three to five years to effect a cure. Most cases got well, with motion at the site of the disease; motion was likely to be better in the cervical or cervicodorsal region. It was poorer or there was very little at from the fourth to the twelfth dorsal vertebra.

Radiographs of Argyrol or Collargol Injections of the Urinary Tract.—Dr. HENRY DAWSON FURNISS of New York read this paper and gave a lantern slide demonstration. Argyrol, 10 to 50 per cent., and collargol, 5 to 25 per cent., were substances most generally used, as these solutions mixed readily with urine. In case of stone that had lodged in the ureter at a point for any length of time there was always a dilatation above it. Here they obtained the relation of the shadow suspected of being the stone and its relations to the ureter and the dilatation above. In cases of floating kidney, with symptoms of renal pain, they had nearly always found some dilatation of the renal pelvis. In renal tumors encroaching upon the kidney pelvis the amount and degree of distortion was graphically depicted. This was of great differential diagnostic importance. During two years he had seen five cases of three ureters and one of four. The method had been useful in the determination of stricture, both of the upper and lower ends of the ureters. They had had several cases of obstruction of the ureter near the pelvis of the kidney. It occurred in the forward and downward direction. They had had ten cases of stricture at the vesical end of the ureter. Nearly all of this work had been done by Dr. Leopold Jaches. The technique was as follows: The patient took 1½ ounces of castor oil the night before and the next morning tea, coffee, or broth. Radiographs were then first made of the entire urinary tract before any injection was given. This was to determine the presence or absence of stones. The suspected side was then catheterized to the renal pelvis. The patient was then put into position and the compression diaphragm adjusted over the area to be radiographed. The silver salt was then introduced. After two or three minutes the exposure was made.

CLINICAL INDICATIONS FOR DIRECT TRANSFUSION OF BLOOD, WITH THE AUTHOR'S TECHNIQUE.*

By A. L. SORESI, M.D.,

NEW YORK.

DIRECT transfusion of blood should interest not only the surgeon as formerly, but the general practitioner as well. Although the procedure of transfusing blood belongs to the domain of surgery, the general practitioner should have as clear an idea as possible nowadays of its clinical and curative value; a number of patients who could derive great benefit from it, when indicated and properly performed, belonging to the domain of the family physician.

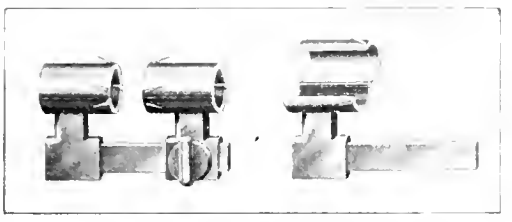

Fig. 1.—The complete Soresi instrument; the figure on the right shows how the instrument opens on a hinge.

It is not possible yet to formulate any final conclusion as to its value; no man has had enough cases to enable him to do so. One thing I can affirm from the experience gained in my experimental work on animals and twenty-five transfusions on human beings is that transfusion performed with the method to be described later is absolutely safe for both donor and recipient, and that there is the positive certainty that blood will always flow freely from the blood-vessel of the donor to the blood-vessel of the recipient, so that technically transfusion is easy to perform and absolutely perfect. It would take too much space to give a detailed history of the twenty-five cases in which I have performed transfusion; in the majority, having been called by other physicians, I will only mention the pathological condition which caused dangerous symptoms that could be benefited by transfusion. Two ruptured ectopic pregnancies, five patients necessitating an operation on the biliary tract, one pneumonia, two cases of hemorrhage in typhoid fever, one ulcer and one cancer of the stomach, three miscarriages, one delayed expulsion of placenta, one sarcoma of leg, one large ovarian cyst, one large myoma necessitating hysterectomy, one carcinoma of sigmoid, one asphyxia from illuminating gas, one Bright's disease, one bleeding hemorrhoids, three severe post-operative shock. In six other cases in which I was called in consultation I thought transfusion should not be resorted to; in two cases the patients were suffering from pernicious anemia, another one was a case of advanced and inoperable cancer of the uterus, in three others the would-be donors were, according to my judgment, in too poor condition, so that their blood would not have greatly benefited the patient, and they might have suffered from its loss. In a few instances I was convinced that transfusion would not benefit the patients, but some of the relatives were so anxious to try it as a last resort that, there not being any danger for the donor, I thought it was only humane to satisfy their wishes.

As seen at a glance the cases can be divided into two classes: in one, the patients needed to have replaced the blood lost through hemorrhages; in the other the blood was used as a therapeutic agent, to better the condition disturbed by a pathological process, and to accelerate the final recovery; while in some both indications were present.

Very gratifying results have been obtained in hemorrhage from all causes, provided the condition that caused the hemorrhage was removed. The important problems of treating hemorrhage lay in the nature of the hemorrhage, and in its gravity *per se*, and in relation to each patient. The bleeding may come from large blood-vessels easily accessible, or which require a surgical operation to be reached; or there may be oozing from capillaries, such as from ulcers of the stomach and intestines, hemoptysis, bleeding from the biliary tracts after operations on the same, in hemophilia, etc. In the former class, after tying the bleeding blood vessels, the indication is to replace the liquid tissue lost; in the second class when surgical procedures cannot be resorted to, the blood is transfused not only as a liquid, but as a therapeutic agent which may stop further bleeding. Keeping these considerations in mind, the first problem to be answered is, "When is saline solution sufficient, and when is direct transfusion indicated?"

It is clear that when the hemorrhage comes from oozing from tissues or ruptured small capillaries, and bleeding is frequent, severe, and repeated, it is because there is lack of coagulability of the blood. Whether this happens because the blood does not

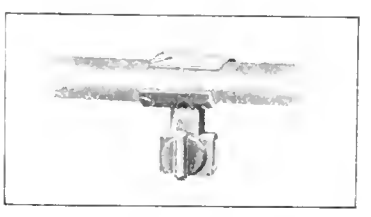

Fig. 2.—Showing how the blood-vessel is laid in the cylinder

contain enough of the principles that make it coagulate, which are not yet well known, or because it does not stimulate the small blood-vessels and capillaries to contract, it is a fact that such conditions are present in the normal healthy blood, and direct

*Read by invitation at the meeting of the Brooklyn Medical Society, February 16, 1912.

transfusion is thereby indicated, because saline solution will only dilute the active principles which cause coagulation, and therefore retard or oppose the same. In hemorrhages caused by a condition which can be absolutely cured surgically, such as

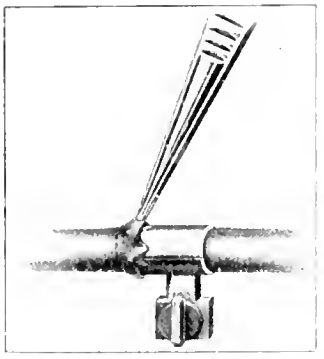

Fig. 3.—Showing how the blood vessel is cuffed over the hooks while blood is still flowing in it; the dotted line shows where the vessel must be cut.

a wound of a blood-vessel, ruptured ectopic pregnancy, etc., saline solution is in the great majority of cases sufficient. Blood transfusion should be employed only when the loss of blood has been very severe, and shock is present, and the hemopoietic organs would be unable to supply in a reasonable time new active elements of the blood which must carry on the work of general metabolism. So it is clear that, if the patient is young and strong, he will be able to stand a loss of blood greater than a person in poor health and anemic, and the severity of the hemorrhage must be judged on these lines: what is very dangerous for an anemic person would hardly be felt by a vigorous, healthy youngster. I give an example which will make things clear: Loss of a certain amount of money might be the ruin of a poor person, and a matter of absolute indifference to a wealthy one. Transfusion will not help a patient who has lost a great amount of blood and has not ingested any liquid for a certain time; his external blood-vessels especially will be contracted, and the blood transfused either from an artery or a vein of the donor will not pass into his vascular system. The old surgeons suspected this and tried to force the blood in the vascular system either with pumps or by using the carotid artery of human beings or animals, so as to make it reach the heart, which would put it in circulation. There is no need of insisting that such a practice would be very dangerous. The physician must know that there is a limitation to the specificity of the blood in treating hemorrhages.

In my series of cases transfusion, although successful technically, did not help the patient in one case of hemorrhage from miscarriage, and in another from ulceration of the intestines in typhoid fever; the patients died while transfusion was going on. The other miscarriage cases were saved and in the other typhoid fever patient the hemoglobin from twenty per cent. rose to fifty, and kept so to the end of the disease without any new hemorrhage. I will discuss later the cases of hemorrhage and shock which have been operated upon.

Another series of patients can be made of those in whom the blood was used as a therapeutic agent exclusively, no hemorrhage having occurred, as in the cases of asphyxia, pneumonia, and Bright's disease; in these cases the system was loaded with poisonous products, such as those found in those pathological conditions. The therapeutic principle was to bleed the patient while new blood was transfused. Transfusion was performed, using the blood-vessels of the arm, and blood-letting from a vein of the leg. In the cases of asphyxia and of pneumonia, the patients derived benefit from transfusion; a remarkable fact is that it was very hard to obtain blood from the patient's vein; in the Bright's disease case transfusion was useless, and performed only because the brother of the patient insisted on having it tried as a last resort, patient being only thirty-two years old. I would not dare to draw any conclusion as to the benefit that can be derived from transfusion and blood-letting combined in pneumonia, but I think the subject worthy of study.

We will come to the last series—patients who have been transfused and had to undergo some surgical operations. Of this series there are two classes: in one the patients had lost prior to the operation a great amount of blood; in the other transfusion had been done to prevent or cure shock, hemorrhage, or other complications which might arise from the poor condition of the patient prior to and after the operation. In the three severe cases of postoperative shock transfusion was useful in only one; the other two patients died, one after about forty-eight hours, the other two hours after transfusion; both patients had received previously saline solution and one blood serum. The two cases of ruptured ectopic pregnancy were helped by transfusion and recovered; of the three cases of miscarriage and placenta previa, one died as said above.

I have come to the conclusion that transfusion should be performed in any case which requires operation, during the operation. Many patients could be saved if the shock which is caused by the anesthetic and hemorrhage during operation could be prevented; this is especially true of cases requiring operations on the biliary tract, pylorus, pancreas, or for large tumors of abdominal organs. I feel positive that in these cases transfusion performed during the operation is really a life-saving procedure. Of the five cases of operation on the biliary tract two patients died: transfusion in one was performed three days after operation; blood serum and saline solution had been used previously; in the other transfusion was performed five hours after operation and the patient died a few hours later. In the other three transfusion was performed during the operation, and the patients made an uneventful recovery, although one had only thirty per cent. hemoglobin before the operation: in none did postoperative hemorrhage occur. The importance of transfusing blood while the operation is going on lies in the fact that shock is pre-

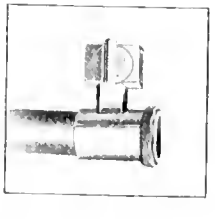

Fig. 4.—Appearance of the blood-vessel after being cut.

vented, because new fresh blood is coming in while operative hemorrhage occurs; the effect of the anesthetic is lessened, and in cases of operations on the biliary tract, pylorus, and pancreas, the new blood prevents postoperative hemorrhage.

Of all the other cases it can be said that transfusion was a great help to the patients, their hemoglobin increased after the operation, and they made uneventful recoveries. As a conclusion I think that when a patient is in poor health conditions his hemo-

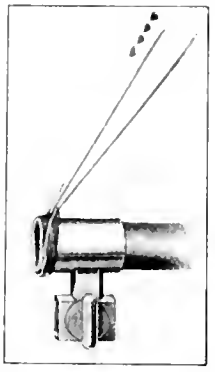

Fig. 5.—Showing how easily the intima is completely everted.

globin is below fifty per cent., and he has to undergo a severe operation, transfusion will help him to final recovery and very probably save his life. Transfusion is absolutely contraindicated in pernicious anemia and in anemias caused by malignant diseases unless the cause is removed.

As I want to make a complete study of transfusion I will be thankful for anyone reporting to me the results obtained; and I am willing to perform the same, of course without any charge, for any hospital patient requiring it.

I will limit myself to the description of the technique of transfusion from vein to vein, because I have lately been so well satisfied with it that I do not see any use of sacrificing an artery when a vein of both donor and recipient can be advantageously used.

The technique of using the radial artery of the donor is identical with the technique described for the vein. The objection to using venous blood I think is absolutely worthless. The arterial blood of the donor would become venous immediately after transfusion, because it has to go into the vein of the recipient, and as long as the blood has to go into the venous system of the recipient I think there is an advantage in using venous blood from the donor, because the two bloods will be more homogeneous.

My instrument is composed of two small metal cylinders, about three mm. in diameter, which are put and held together by means of a small bar and screw (Fig. 1). Each cylinder is opened on its longitudinal axis by a simple hinge (Fig. 1), and at one end a little below the edge is encircled by a crown of six small hooks, the points of which are turned toward the other end, as shown by the illustrations 1 and 2. In order to make the instrument durable the same is made of sterling silver; it is very easily kept clean, and can be sterilized by simply boiling it. The hooks are made of very hard gold and are very sharp and must be kept so, because they must readily catch the blood-vessels when cuffed over them. It is easy to keep the hooks sharp by not injuring them, and in case they are not very sharp they can be filed with a small jeweler's file. I think that the illustrations make the procedure very plain to anyone who will take the trouble to follow them.

The blood-vessels of both donor and recipient must be isolated for about six or seven cm. and care must be taken not to injure them by pulling on them too hard, or by any other rough handling, which is, moreover, absolutely unnecessary. Every lateral branch is ligated about two or three mm. from the main trunk. The isolated blood-vessel is lifted up and one of the two cylinders is opened and the blood-vessel laid in it (Fig. 2). The instrument is then closed. With a thumb forceps the blood-vessel is cuffed over the hooks of the cylinder (Fig. 3). The cuffing of the blood-vessel must begin over the two hooks which are near the opening and are the only ones shown in Figs. 1B and 2, so that, when the blood-vessel is so cuffed over the hooks, the instrument cannot open. The cuffing is done with small thumb forceps, the points of which must be blunt and the two blades grooved on the inside, so as to enable the surgeon to catch the blood-vessel firmly without puncturing it. Sometimes on account of having chosen a blood-vessel of not very large size, it is difficult to cuff it all around the cylinder as shown in Fig. 3. In Fig. 3 is shown the ideal way of cuffing the blood-vessel over the hooks, that is, starting from the two hooks near the opening and finishing as shown in the illustration, with the one nearest to the opening; but if any difficulty is experienced in doing so, the surgeon need not worry, for as long as the blood-vessel is cuffed over the two hooks near the opening, and one or more hooks around, that is entirely sufficient, because when the blood-vessel is cut it will not retract, and it will be easy to finish the eversion of the intima, when the vessel is cut as explained later. Exactly the same procedure is repeated for the blood-vessel of the donor. The two cylinders have to be put with the screw and the bar toward the operator, so as to make twisting of the blood-vessel absolutely impossible. When both blood-vessels have been cuffed over the hooks, the limbs of the donor and recipient are closely approximated. First the vein of the recipient is cut about 1 mm. from the edge of the cylinder as shown in the dotted line of Fig. 3. The other end is clamped and ligated later. When the blood-vessel is cut the appearance of same will often be as shown in Fig. 4, that is the intima will not always drop back completely. This is very easily and rapidly accomplished by pulling down with the thumb forceps (Fig. 5) the cut edge of the blood-vessel, so that its appearance will be as shown in Figs. 6, 7, and 8. The vein of the recipient everted over the cylinder will be covered immediately with gauze soaked in warm saline solution. The vein of the donor will

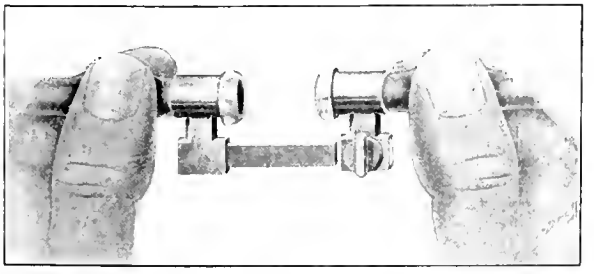

Fig. 6.—How to get hold of the blood-vessels to prevent them from bleeding, and how the bar of one cylinder is introduced into the corresponding hole of the other.

be cut in the same way, while the assistant makes pressure on the side whence the blood is coming with his index and thumb fingers as shown in Fig. 6. When the blood-vessels of the donor and of the recipient are everted over the cylinders the

surgeon will place the thumb and index finger of each hand around the blood-vessels close to the cylinders, as shown in Fig. 6, and so prevent bleeding without injuring the vessels in any way. The bar of one of the cylinders will then be introduced into

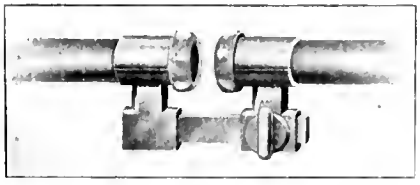

Fig. 7.—Showing how to keep the blood-vessels so that blood flows from them, assuring the operator that the blood is freely flowing before the ends are approximated, as shown in Fig. 8.

the corresponding hole of the other cylinder, the pressure of the fingers released (Fig. 7) so that some blood will flow from the vessels. *In this way the surgeon is positively sure that there is no clotting and that the blood is actually flowing from the vessel of the donor to the vessel of the recipient.* When the surgeon has assured himself that the blood is flowing freely, by leaving for a few moments the blood-vessels as shown in Fig. 7, he will approximate them closely as shown in Fig. 8. *While the blood is flowing* tighten the screw, and the procedure is finished. It is easily understood that the blood will flow from the vein of the donor to that of the recipient, as though the two were only one continuous blood-vessel.

When performing transfusion between adults, the veins of the forearm of both donor and recipient can be used as shown in Fig. 9. It has to be remembered that the limbs of both of them must be put in the same direction, because the blood is flowing from the periphery of the donor toward the heart of the recipient, and in order to help the flowing of the blood the donor is advantageously put on a higher plane so that gravity helps it. While performing transfusion during a surgical operation, if the use of the forearms should interfere with the work of the surgeon, the vein of the lower limbs for both donor and recipient or for only one of them, according to circumstances, can be used. In transfusing from adults to children, a vein of the thigh of the child must be used, and the most accessible vein is the external saphenous, and the position to be given to both donor and recipient can be as the one shown in Fig. 10. If the external saphenous be too small the femoral vein has to be used. The former must be preferred, when possible, on account of its accessibility, and the fact that no other important structure can be injured.

There are certain precautions on which I insist when performing transfusion from vein to vein,

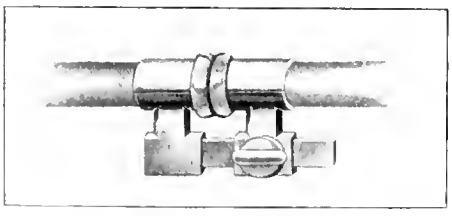

Fig. 8.—[illegible] approximated; screw tightened; procedure completed.

and unless the surgeon conforms to these rules the procedure will be unsuccessful. The blood-vessels of both donor and recipient must be kept constantly covered with gauze soaked in warm saline solution, which must be kept warm by pouring on new warm solution all the time. *This is absolutely indispensable, because in order to have the blood flow from the vein of the donor to the vein of the recipient the veins must be put in the same conditions as they are in the normal human body, that is, they must be surrounded by a warm moist medium.* If left exposed to the air the veins will contract and the *vis a tergo* of the blood in the vessels of the recipient will not allow the blood of the donor to enter the vascular system of the recipient himself. I insist again on this point, because I have seen surgeons looking all the time at the anastomosed vein, and afterward complain that the blood was not running from the donor to the recipient. Once the surgeon is sure that, when he has put the two blood-vessels in contact, the blood was running freely from the vessel of the donor, it is useless to look at the blood-vessels. The only way to assure oneself that transfusion is going along satisfactorily is the improving condition of the patient and the hemoglobin test. By starting the hemoglobin test with any one of the simple methods of blotting paper and comparing it with the hemoglobin scale, before transfusion is commenced, and examining the blood at frequent intervals of about five minutes, the surgeon will know that the blood of the donor is passing into the system of the recipient.

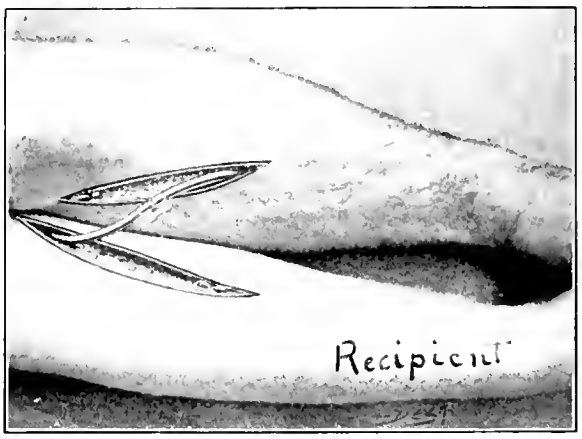

Fig. 9.—Position of the arms of the donor and recipient when transfusion is made from vein to vein.

Another important point is that there must be no tension between the two blood-vessels.

The time to stop the flowing of the blood from the donor to the recipient must be left to the judgment of the surgeon, but I should say that when the hemoglobin of the recipient has been increased by from twenty-five to thirty per cent., it is time to stop. One thing that the surgeon must be careful about is the condition of the donor. He must be put in a very comfortable position, because otherwise, by getting fatigued, will need to change it. He must be laid on a table well padded, with the head on the same level with the body or even a little lower if necessary. The limbs of both donor and recipient must be closely approximated, but in a comfortable way, in order to avoid stretching of the anastomosed blood-vessels and any movement on the part of the donor. The donor must be watched very carefully in order to detect any sign of weakening on his part, so that his life may not be put in danger. The care that we give to the donor is the same as we would give to anyone who was suffering a severe hemorrhage, and if the surgeon keeps this point in mind he will understand that at the least sign of weakening on the part of the donor transfusion should be immediately

stopped and saline solution if necessary given him by proctoclysis, hypodermoclysis, or simply by giving him some water with whiskey, brandy, or coffee, putting his head low and keeping him in a horizontal position as long as the surgeon thinks it is necessary to keep him so. I must warn the surgeon against the danger of the rapid passage of the blood from the donor to the recipient. This can occur especially in cases of severe hemorrhage, because a few minutes after transfusion has been started the vascular system of the recipient actually sucks the blood from the donor in order to supply the necessary amount of liquid that is indispensable for its own work, and the danger of this condition is acute dilatation of the heart on the part of the recipient and severe shock to the donor. This has never occurred to me when using vein-to-vein transfusion. I think this is one of the advantages of using vein-to-vein instead of artery-to-vein transfusion, because the blood of the donor is not under a higher pressure, and the passage is uniform and slow.

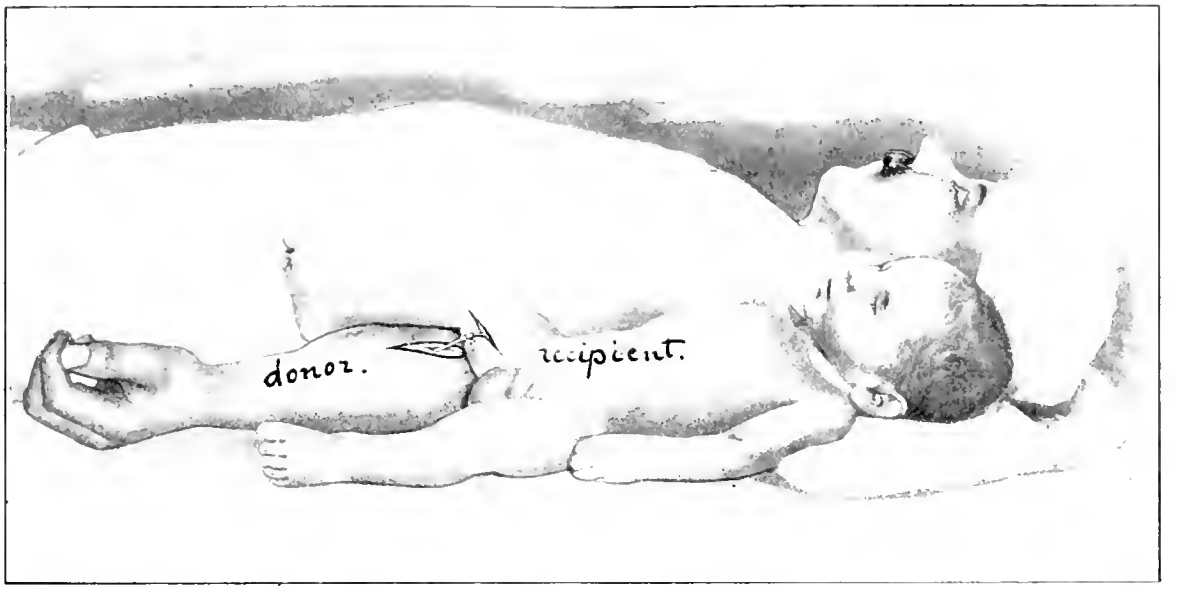

Fig. 10.—Position of the child (recipient) and adult (donor) in arm-to-leg transfusion.

I will call the attention of the surgeon to the fact that in the method just described the anastomosis of the two blood-vessels takes place between the intimas of the two vessels which have in no way been traumatized, because the instruments which traumatize the blood-vessels over the point of the anastomosis, such as hooks, needles, and thread, are not used at all. Another point to which I want to call the attention of the surgeon is the absolute safety of the procedure. There is no danger of injuring the blood-vessel of either donor or recipient and so cause clotting, because no serrefines, clamps, or anything else intended to stop the flow of the blood while preparing for the anastomosis have to be used.

Finally the surgeon has the absolute certainty that the blood from the donor will run into the blood-vessels of the recipient, because, as explained above, before he brings the two vessels in contact, he lets the blood flow from the cut vessels, so that he is sure that there is no clotting or any other obstacle which will interfere with the free flow of the blood; while with any of the other methods no one can be sure that when releasing the serrefines or the clamps the blood will flow from the donor to the recipient, because the anastomosis has to be completed, while the clamps or serrefines are in place, and this requires sometimes a considerable time. That with other methods the blood frequently does not flow after the anastomosis is completed has been verified by everyone who has used them and followed the advice given by their authors to massage the blood-vessels. Such procedure cannot be condemned strongly enough, even if no serious accident has been reported from it. There is a great possibility that by massaging the veins the emboli so produced might block an important blood-vessel, and the risk is so apparent that I do not think it is necessary to do more than mention it. Local anesthesia with cocaine solution 1 to 500 is sufficient. No adrenalin should be added on account of its action in causing contraction of the blood-vessels.

75 West Fifty-fifth Street.

SOME SUGGESTIONS ON THE TREATMENT OF INTRANASAL CONDITIONS.

By A. EMIL SCHMITT, M.D.,

NEW YORK.

INSTRUCTOR IN OPERATIVE SURGERY, COLUMBIA UNIVERSITY; ATTENDING SURGEON GERMAN HOSPITAL, O.P.D.; MEDICAL ADVISER ETHICAL CULTURE SCHOOL, ETC., ETC.

In acute and chronic rhinitis and nasopharyngitis more or less frequent cleansing of the nasal cavity is accepted as a proper procedure. Heretofore this has been carried out by the patient by the use of sprays or douching or sniffing of salt water or of solutions with combinations of drugs, such as sodium chloride and bicarbonate with boric acid; or as found in the various detergent solutions usually containing thymol, eucalyptol, sodium chloride, bicarbonate, and biborate, with or without glycerine and alcohol. With a dry condition of the membranes, solutions containing glycerin seem to be contraindicated and solutions free from glycerin and alcohol are advisable.

When using the nasal douche, the patient should be instructed to hold his head sideways, over a basin, instead of backwards, and to apply the douche to one nostril and permit the fluid to pass through and run out of the other nostril. The mouth should be kept open in order to fix the soft

palate and allow breathing to go on through this passage. The patient is cautioned not to swallow, which would relax the palate and cause the fluid to enter the pharynx or larynx and produce a paroxysm of cough. After clearing the nose the

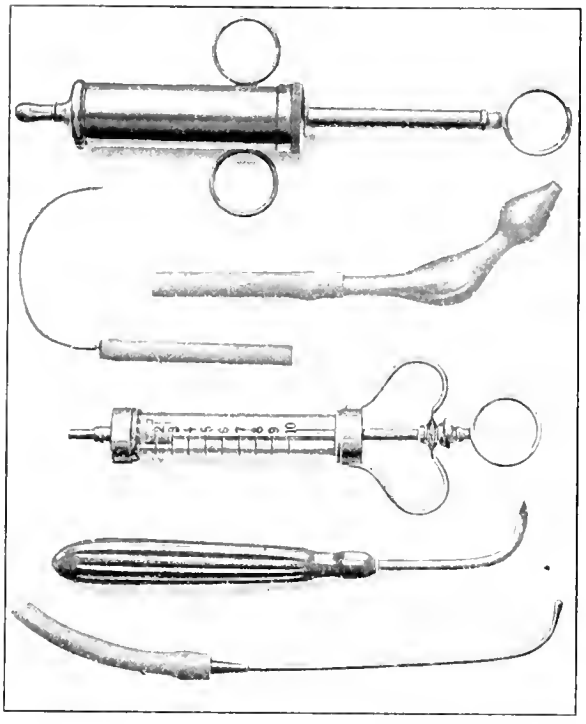

Fig. 1.—Suction pump, glass nozzle, probe cannula, irrigating syringe, trocar for maxillary antrum, cannula for trocar opening.

douche is refilled and applied to the other nostril; the fluid then flows in the opposite direction. This is less harmful than the use of an atomizer, as it does not so much injure the epithelial lining.

Far superior to any spraying or douching of the nose or the nasopharynx and, especially for prolonged use, is the cleansing of the nose from behind forward. This might be called nasopharyngeal gargling and is performed as follows: After brushing the teeth and rinsing the mouth, the throat is gargled to free it from food particles and mucus, which would be liable to be projected into the nose. After taking a long breath, a mouthful of the cleansing solution chosen is taken, the head is thrown back, as with ordinary gargling, but instead of fixing the palate and projecting the air through the mouth, as in ordinary gargling, the palate is relaxed and the air is blown through the nose with the same gurgling force. The fluid thus mounts higher and higher into the nose until it is discharged from the anterior nares. The head is now thrown forward over the basin to allow the fluid to flow out. This procedure is repeated three or five times until the nose is thoroughly cleared and open. Spraying the nasopharyngeal space is usually most unsatisfactory on account of the uncontrolability of the soft palate, the constriction of the nasopharyngeal space, due to the spasmodic contraction of the muscles of that region, and the possibility of trauma from upward projecting nozzles necessary for the purpose. On the other hand, the nasopharyngeal gargling just described is as harmless to all the tissues as douching and far more effective because it reaches all the crevices and, on account of the natural slant of the turbinals, the fluid, passing from behind forward, cleanses both the inferior and superior surfaces of these bodies and flushes the meatuses as well as the septum. Besides this there is no injury to the tissues, as with the projecting spray or nozzle of the atomizer. The nasopharynx and the posterior nares, which are the most important places for harboring disease germs and infectious material, are reached more effectively than is possible by any other method.

This procedure, so beneficial as a curative agent, is far more so as a prophylactic measure. From personal experience it has been determined that with its daily application as a part of the morning toilet, severe inflammatory processes which previously thereto had been of most frequent occurrence, have been prevented and aborted over a long period of months. The procedure requires some experience and skill before it can be acquired, but if each step of the instructions is faithfully carried out and persisted in, success eventually will come and the benefits thereby derived will many times repay the effort used in acquiring it.

The objection may be raised that with a forcible projection of fluid into the nasopharynx the solution might enter the relaxed orifices of the Eustachian tubes and cause middle-ear infection. If any fluid should enter the tube a very simple procedure will withdraw it. This consists in compressing the nostrils with thumb and forefinger of one hand and at the same time swallowing a glass of water without taking a breath. This will produce sufficient suction to withdraw the fluid and thus clear the tubes. This is the method I have used for several years in all otitis-media cases, having it repeated frequently during the day for clearing the tubes of secretions and causing an exchange of air in the middle ear.

In cases of severe rhinitis due to ordinary infection or more particularly to influenza, extension to the sinuses often occurs. The ostia of the sinuses are so situated, that for ordinary purposes they are in the most protected places to prevent entrance of extraneous matter; but if infection enters and a secretion in the form of serum or pus is present, the ostia are placed most disadvantageously for proper drainage. Nevertheless, in carrying out conservative treatment it is possible, by resorting to the posture of the head, to have the ostia placed at a most dependent point, and then by means of

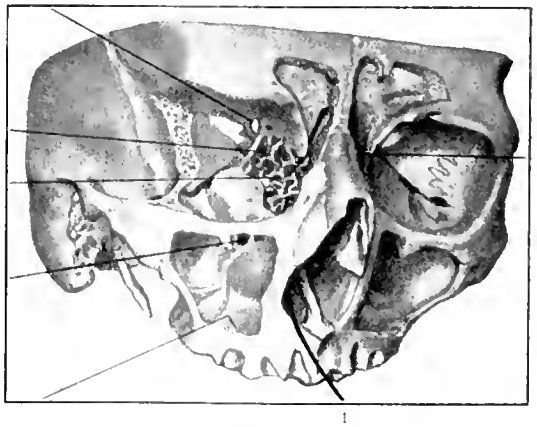

Fig. 2.—1, Probe cannula passed through infundibulum and nasofrontal duct into frontal sinus. 2, Ostium of maxillary antrum is seen at upper inner angle of sinus. 3, 3, Ethmoidal cells are seen with orbital wall removed.

suction, or irrigation and medication combined with suction, to defer operative procedure or to render such unnecessary.

In inflammations of the nose that have extended through the hiatus semilunaris into the nasofrontal

duct or into the ostium of the maxillary antr[illegible] through the ostium of the sphenoidal sinus. I h[illegible] found the following procedure most effective [illegible] nasal membrane receives an application of one [illegible] the penetrating non-irritating silver preparation[illegible]

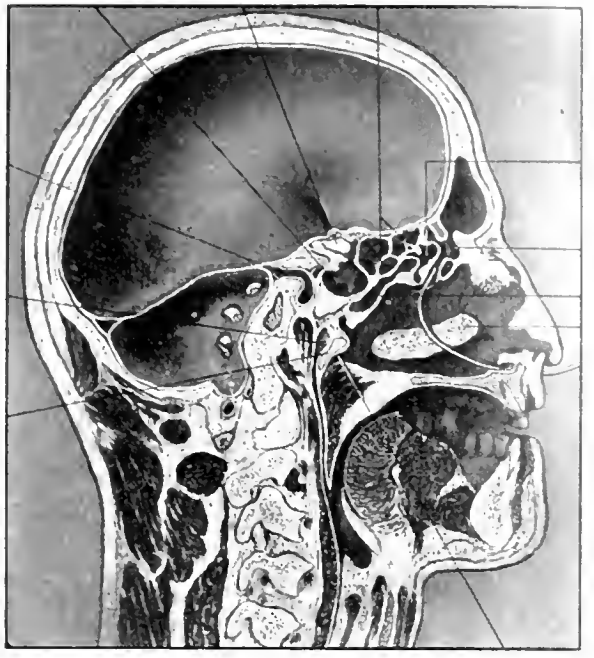

Fig. 3.—Middle turbinal removed to show probe [illegible] through hiatus semilunaris and infundibulum. The frontal sinus communicates with the nose indirectly through the ethmoidal cells. Removal of ethmoidal cells would be necessary to penetrate into the sinus with a cannula.

It is then sprayed or douched with a detergent solution, as would be done ordinarily for disinfection and treatment of acute or chronically inflamed membranes. In the case of frontal sinusitis, cocain is then applied to the region of the nasofrontal duct, particularly on account of its non-irritating, astringent effect. Thereafter suction is carried out by means of a glass nozzle and suction pump, the former connected with the latter by a small piece of rubber tubing, thereby minimizing the shock when the piston is brought down. The glass nozzle has an ampulla below which catches the secretions and prevents them from entering the pump. The amount of suction is regulated by compressing the nostril of the other side, the inrush of air counteracting the suction as well as sweeping the secretions from the nostrils into the glass nozzle. The glass nozzle completely clogs the nostril into which it is inserted and the pressure of the finger against the other nostril occludes both openings, preventing access of air from this source, otherwise no negative pressure would result. The patient is instructed to take a few deep inspirations and after expelling the air to keep his lips tightly closed. The suction pump is now put into action and continued until the patient shows distress in the region of the sinuses or is again compelled to take breath. The interval permits cleansing of the nozzle which by this time has received some of the secretion from the nose or even from the sinus. The suction is to be repeated from four to six times on the affected side, or on both sides if both sinuses are involved. The treatment is repeated every second or third day according to the acuteness of the condition. Relief usually is immediate and lasts for many hours, each subsequent treatment prolonging the time the patient is free from pain. We thus effect not only withdrawal of retained secretions and an exchange of air in the sinuses, but also a temporary hyperemia which is most effective in all inflammatory processes. At first only mucus from the nose or mucus, mucopus, or pure pus from the sinus itself may appear in the ampulla of the glass nasal nozzle. If pure pus appears at the first and the second treatment, this is rapidly changed on subsequent treatments to mucopus or pure mucus with a corresponding relief of pain or discomfort over and within the sinus. The patient is instructed repeatedly to use suction at home by means of compressing the nostrils and swallowing with or without fluids. This, with internal medication in the form of salicylates, purging, drinking of alkaline waters, douching or gargling the nose, and the application of heat or cold to the affected sinus will effect a rapid cure.

In the treatment of inflammation of the maxillary antrum a similar procedure is carried out, and here the location of the opening of the sinus, being situated at the upper inner angle of the sinus and requiring a dependent position of the head if drainage through the ostium is to be effected, is taken into consideration. During suction the patient must lie on his side with the head as low as is consistent with comfort, the affected side being uppermost, the maneuvers with the suction pump and nozzle being the same as described for the frontal sinus. The posture for effective suction treatment with sphenoidal sinusitis should be with the head forward and low down, the ostium being situated well up on its anterior wall. If suction and cleansing and internal medication do not suffice for clearing the condition, irrigation combined with other treatment becomes necessary.

In frontal sinusitis a probe cannula with a di-

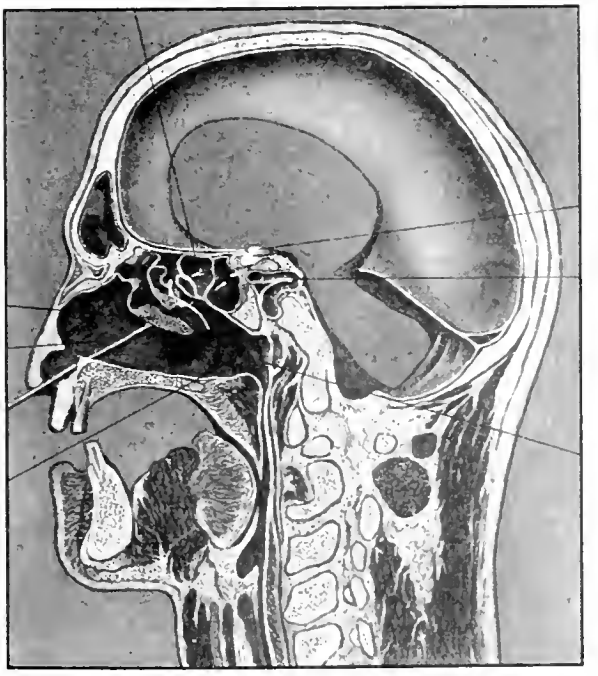

Fig. 4.—Probe cannula introduced at an angle of 45° with the floor of the nose into the ostium of the sphenoidal sinus. Section represents middle turbinal, ethmoid and sphenoid cells and septum lifted from previous specimen.

ameter of eight centimeters and bent in the form of a semicircle is introduced, with the aid of the nasal speculum and good illumination, into the middle meatus, through the hiatus semilunaris upward and forward along the infundibulum and

nasofrontal duct into the frontal sinus. The end of the instrument will be free in the sinus and permit thorough irrigation and medication of the part. The cannula should be of the smallest size and of good length, and it is well first to bend the tip to conform to the side of the affected sinus. Usually the anterior part of the middle turbinal forms a fold or curtain or bridge where it is attached to the lateral wall of the nose. It is behind this fold that the cannula must pass into the nasofrontal duct. Sometimes the hiatus semilunaris can be seen for a good distance upward, and the cannula can be introduced at its upper part instead of traversing the entire length of the infundibulum. The medicating and irrigating fluids are now introduced through the cannula to which a small piece of rubber tubing is attached. This serves for the easy application of the syringe, the patient steadying the cannula with two fingers while the irrigating and medicating fluids are being introduced. This is immediately followed by suction heretofore described. If introduction through the natural passage is impossible, it is sometimes necessary to remove the anterior part of the middle turbinal, especially the part forming the bridge above mentioned and also the air cells contiguous to the nasofrontal duct.

In the case of the maxillary antrum the probe cannula has its tip bent at right angles for a distance of half an inch. This is introduced through the middle meatus and hiatus semilunaris to the lowest or posterior end of the infundibulum to pass through the ostium into the antrum itself. Medication and irrigation are carried out in the same manner as in frontal sinusitis, with the patient in the erect posture and suction in the recumbent posture with the patient on his side and the head low down.

If a decayed tooth projecting into the antrum is the cause of the sinusitis, it will be necessary to remove the offending root; but it is preferable to make the intranasal opening for treatment and drainage instead of a large opening through the socket. It is true that in the latter instance a more dependent point in the antrum can be reached, but reinfection from the mouth prolongs the process. If on the other hand the opening through the socket is plugged between treatments to prevent infection, retention of the secretions has the same disadvantage as in the case of constant drainage but reinfection without the plug.

With involvement of the sphenoidal sinus, a cannula with the tip slightly bent is passed upward and backward, at an angle of 45 per cent. with the floor of the nose through the ostium into the sinus itself. The ostium is at times located a little distance out from the septum. This is medicated and irrigated as in the case of the other sinuses but should be followed by air pressure with the head bent forward and low down and suction carried out in the same posture.

If introduction of the cannula into the frontal sinus is unsuccessful owing to the fact that the nasofrontal duct does not directly communicate with the meatus but opens into an ethmoidal cell, a passage is made by removing the upper and anterior portion of the middle turbinal and contiguous ethmoidal cells, until a sufficiently large opening is made to introduce a cannula and to give sufficient drainage.

When the ostium of the maxillary antrum is inaccessible for irrigation or insufficiently open for proper drainage, an artificial opening is made about half way back through the lateral wall of the nose as close to the floor as possible. A trocar one half centimeter in thickness, with the tip three and a half centimeters long bent at right angles to the shaft, is used for the purpose. In the middle of the lateral wall the mucus membrane and the parchment-like bone can be pierced readily. The part is cocainized, the instrument is introduced perpendicularly, and then so turned that the point impinges on the lateral wall. Pressure is now made outward and as the handle is moved upward and downward a good-sized opening is effected with the least degree of pain. Through this opening the cannula is now introduced and treatment is given as before described. Medication and irrigation are repeated for a number of sittings, the cavity draining between times; or the patient is instructed to resort to irrigations at home, introducing the cannula himself.

If the opening cannot be kept patent sufficiently long to effect a cure—as it usually heals up within two weeks—more of the wall can be removed by means of a forceps or with an instrument having the same curve as the trocar, but with a fraize-like end, which with a similar movement will break up and carry away a greater amount of bone and produce a more permanent opening.

If the ostium of the sphenoidal sinus cannot be reached, a portion of the middle turbinal must be removed to make it accessible. If the ostium is too small for the introduction of a cannula and for proper drainage, a portion of the entire anterior wall below the ostium must be removed with a drill, chisel, or bone-biting forceps.

Only when the various stages of this more conservative treatment have been found insufficient to effect a cure are more radical methods, with the exposure of the sinuses from without, permissible.

50 Central Park West

A SCIENTIFIC SYSTEM OF ADMINISTERING ETHER.

By RAYMOND C. COBURN, M.A., M.D

NEW YORK.

In an article prepared under the direction of and cooperation with the Anesthesia Commission of the American Medical Association, and published by this commission, the following *disadvantages* of the present day methods of administering ether were set forth:[1]

The closed method: 1. Decreased oxygenation and increased carbon dioxide. 2. Impossibility of regulating the dosage (even approximately) because of the necessity of pouring the ether into the cone or inhaler intermittently. 3. Disagreeable and prolonged induction.

The open drop method: 4. Cold vapor. 5. Incomplete diffusion of vapor because of the close proximity of the application of the ether to the face. 6. Waste of the ether by the exhalations and saturation of the surrounding air with ether vapor. 7. Long period of induction.

It might be added that these are the usual objections urged against each method.

In the apparatus which I have devised especially for the administration of nitrous oxide and oxygen with ether as an adjuvant, and which was described in the *Journal of the American Medical Association*,[2] I have overcome each and every one of these objections except the increased carbon dioxide in rebreathing; but in the light of Henderson's work

on carbon dioxide and its practical application in the administration of anesthetics by numerous anesthetists, it has been practically proven that this heretofore considered disadvantage is, in reality, when properly regulated, a distinct advantage, as respiration and circulation are thereby better maintained and surgical shock either prevented or alleviated.

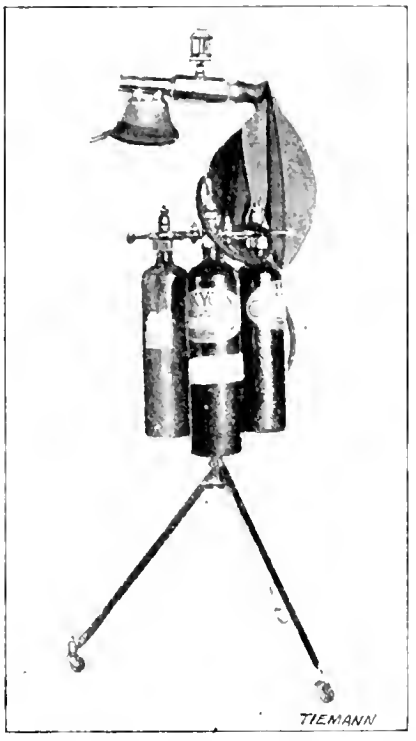

Fig. 1—Coburn Apparatus, with the folding, portable stand and a cylinder each of nitrous oxide, oxygen and carbon dioxide in position, for inducing anesthesia and furnishing either oxygen or carbon dioxide in the closed method.

*1. Proper oxygenation may be secured by allowing a small amount of air to be inspired with each inspiration, or by adding pure oxygen to the rebreathing bag, or by a combination of these two sources of supply of the requisite oxygen. In this manner a superoxygenation of the blood may be maintained throughout the operation if desired.

As carbon dioxide is diffusible it readily transpires through the walls of the capillary blood vessels into the air whenever there is considerable exposure of these vessels. Therefore in abdominal operations, with the viscera exposed, in order to maintain even a normal amount of carbon dioxide in the blood, it is necessary that there be considerable rebreathing or its equivalent; so in this class of operations where it is desirable to maintain a normal or slight excess of carbon dioxide the air supply should be greatly restricted and pure oxygen added direct to the rebreathing bag, or, with the air supply sufficient for proper oxygenation, pure carbon dioxide should be added direct from a cylinder to the bag. With this method of procedure the carbon dioxide retention and the oxygenation of the blood may be easily controlled at all times, as the rebreathing, with its concomitant carbon dioxide retention, or the pure carbon dioxide, and the oxygen supply may thus be completely separated, and each governed according to its own special requirements. A patient undergoing an abdominal operation with the viscera exposed will tolerate to good advantage double the amount of rebreathing that the same patient in the same anesthesia will tolerate before the abdomen is completely opened, or in a separate operation where there is little exposure of the capillary blood vessels, such as in the amputation of a limb and kindred conditions. Accordingly, if the closed method of administering ether is to be placed upon a scientific basis, rebreathing, with its accompanying carbon dioxide retention, or the carbon dioxide gas, and the oxygen supply must be, at certain times at least, under separate control so as to fulfill the widely varying requirements of each of these important but not necessarily correlated factors in the proper maintenance of anesthesia, for otherwise, in abdominal operations and kindred procedure, when the air supply is sufficient for proper oxygenation there is not sufficient rebreathing to retain even a normal amount of carbon dioxide; and when the rebreathing is sufficient to maintain the proper amount of carbon dioxide a sufficient amount of air is not inspired properly to oxygenate the blood. A mixture of carbon dioxide and oxygen may be used, if desired, instead of the pure carbon dioxide. Either the pure or mixed carbon dioxide may, also, be administered in the open method, thereby securing the complete benefits of the carbon dioxide prophylaxis and alleviation of shock, and its other beneficial physiological effects, without rebreathing.

2. This objection I have overcome by what I call "the closed drop method"—the ether being administered drop by drop and the rate of administration under constant sight and complete control of the anesthetist. This continuous and even administration of the anesthetic produces a vapor that is constant in strength and temperature and therefore causes no unnecessary irritation of the upper respiratory passages, as is the case when the ether is poured on in quantities at intervals.

3. It has been the practice in this city for many years to secure a pleasant and rapid induction of anesthesia with either nitrous oxide or ethyl chloride, and the immense, practical, and scientific advantage of this method of procedure is well set forth by Crile[2] and Henderson.[4] Few physicians realize the far-reaching and detrimental effect of preanesthetic fear, and its distinctly pathological basis is clearly shown in the references cited.

4. "In order to ascertain the temperature of the vapor inhaled when ether is administered by the open drop method, I placed a specially constructed and delicately calibrated thermometer within an inch of the gauze in the herein described inhaler—the approximate distance of the patient's respiratory

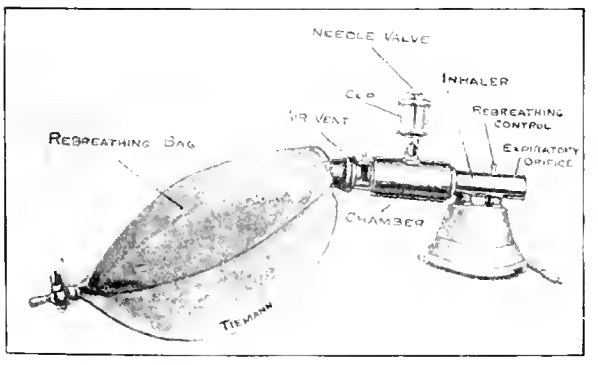

Fig. 2.—Same as Fig. 1, with stand, cylinders and tubing removed, for administering ether by the closed method when oxygen or carbon dioxide is not needed

*This and subsequent numbers refer to the disadvantages outlined by the Anesthesia Commission, and which I have overcome with the exception mentioned

passages from the gauze of the usual open mask—and, since the expirations did not influence the thermometer, this gave the temperature accurately of the inspired vapor. Sufficient ether for a light anesthesia quickly reduced the temperature to 55° F., a moderate anesthesia to 45° F., a deep anesthesia to 35° F., and a profound anesthesia to 32° F., operating room temperature 75° F."[2]

When these observations were made I did not then know that the temperature of inspired ether vapor by the open drop method had ever been previously determined, but I have since learned that Joss reports his observations[5] that ether cools the air inspired through the mask so that it averages 33° F. below the temperature of the room, and the difference is frequently 44° F. during certain periods of the anesthesia. The temperature was often below 32° F. and in one case the thermometer registered below the freezing point for twenty-six minutes.

These observations are reported in a little different language, yet, practically, they are identical.

"After determining the temperature of the cold vapor I attached the electric heater to the ether

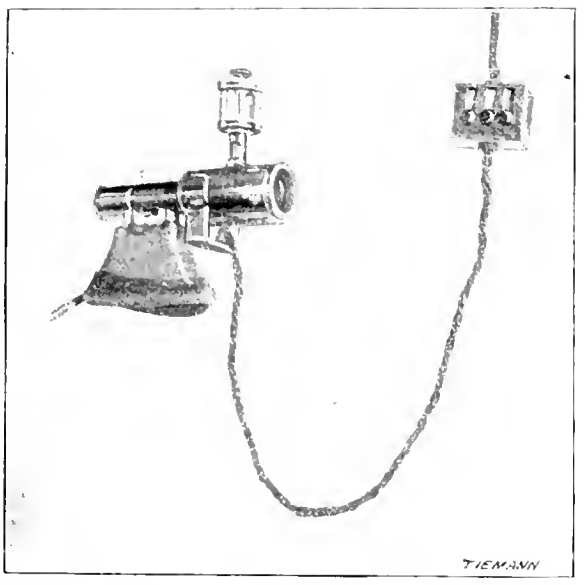

Fig. 3—Same as Fig. 2, with the rebreathing bag removed and the electric heater attached, for administering ether by the open drop method, vapor warm.

chamber and I found the temperature then to vary from 80° F. to 88° F., average 84° F., in a room temperature of 75° F. In other words, the electric heater raised the temperature of the vapor on an average of 42° by the thermometer. But in this apparatus, after passing over the thermometer the vapor passes through three inches of a metal tube maintained at a temperature of about 110° F., which further elevates the temperature of the vapor several degrees, and on account of a low specific heat of gases the vapor was warmed to practically body temperature at the time it was inhaled."[3]

While it would require very extended clinical observation to establish any reliable statistics on the difference in post-operative complications, it can be said with a certainty that when the warm vapor is used the respirations are quieter and smoother, and the secretion of mucus less—facts strongly indicative of less trauma to the respiratory passages. And this is all the more significant when it is recalled that pneumococci and other pathogenic organisms are practically ever present in the respiratory tract and that ether, through its action on the phagocytes, materially weakens the patient's natural defences against infection in general, as well as that against pneumococci in particular.

While the vapor by the closed method is somewhat cold I have detailed that of the open drop method because this is the method that is in the most extensive use at the present time, and because the temperature involved is the most extreme and has previously offered insurmountable obstacles as to control in this respect in any appreciable degree.

5. In the apparatus mentioned the gauze is about three inches from the patient's face, and this insures that the ether vapor and air will be well mixed before being inhaled.

6. As the exhalations escape from the mask without passing over the gauze there is no waste of the anesthetic from this source, and consequently there is no unpleasant saturation of the operating room with ether vapor. It necessarily follows from this that a considerable saving in the cost of the anesthetic results from the prevention of this needless waste.

7. See under 3.

Summary.—A rapid, pleasant induction; a mechanical drop method; a regular, constant administration; a warm, bland vapor; a smooth, even anesthesia; a pliable control of oxygen and carbon dioxide; a real, marked economy; a practical, scientific system of administration.

DEATH FROM RENAL ADENOSARCOMA.

BEING THE FINAL NOTES OF A CASE REPORTED IN THE MEDICAL RECORD, AUGUST 26, 1911.

By VICTOR COX PEDERSEN, A.M., M.D.,

NEW YORK.

In the previous report alluded to in the title, the writer promised to add briefly the notes of the death of the patient, so soon as that expected result might occur. For a brief period after the operation the patient continued to do very well, and hope was felt, as expressed in the original notes, that life might be prolonged for a considerable time. At the end of about three months, however, signs of ascites and of venous obstruction of the lower extremities, more marked on the left than right side, began to appear. The progress of the obstructions was rather rapid and naturally associated with emaciation, as shown in the photograph (Fig. 1). This photograph compared with those which were published in the first paper is really pathetic in its marked changes from a happy, rosy-looking baby to one who was rapidly wasting into dissolution.

A radiograph of the thorax was taken at about this time, and is shown in Fig. 2 herewith. The relapse of the tumor on the left side and upper segment of the abdomen is rather distinctly shown. Before the ascites itself was sufficient to account for embarrassment of breathing and heart action,

these symptoms appeared and augmented rather distinctly. It was desired at this time to take also a radiograph of the abdomen, but the family delayed matters until the weakness was so pronounced in the patient as to render her removal from her tenement house home to the laboratory inadvisable. The circumstance of the absence of the radiograph of the chest is therefore explained in this manner.

The venous obstruction with ascites, swelling, and edema of the lower extremities, especially the left, and embarrassment of the heart and lung action, steadily advanced, combined, of course, with greater and greater emaciation, until the end came almost to a day, six months after the operation, namely, September 28, 1911. Autopsy was denied much to my regret.

This case was briefly reported at the October, 1911, meeting of the Genito-Urinary Section of the New York Academy of Medicine. Dr. Leo Buerger kindly volunteered to make another pathological examination of the kidney for me at the laboratory of the Mount Sinai Hospital. The following are the notes with which he has very courteously furnished me, obligations and thanks for which are hereby gratefully acknowledged.

"No. B1300.—Microscopic examination reveals a mixed tumor in which two types of tissue predominate. A striking feature is the presence of glandular tubules which in places are to be found irregularly interspersed in a spindle-celled stroma; in other places, these have a different relation to the type of growth (spindle cells) in that the connective tissue elements are grouped in smaller and larger alveoli or are solid nests around the glandular elements.

Fig. 1.

The gland tubules are seen mostly in cross-section where they are narrow acini made up of a single layer of cuboidal cells. A narrow basement connective tissue membrane surrounds these tubules often surrounded by a single layer of flattened spindle-cell elements that pass imperceptibly into the surrounding tumor cells. Occasionally these tubules are cut so as to present elongated and slightly convoluted acini.

"The second type of tissue has the general ap-

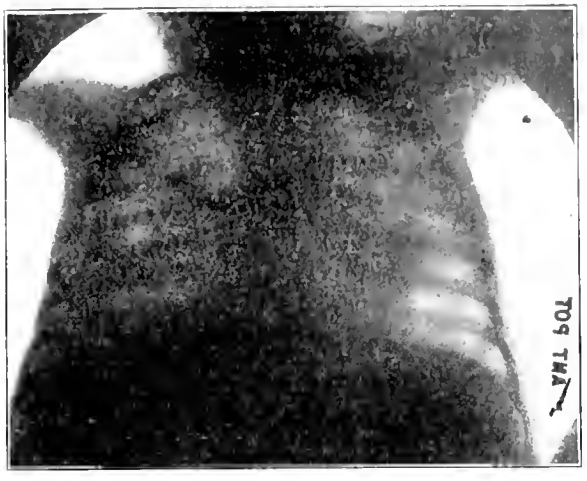

Fig. 2.

pearance of spindle-celled sarcoma of the small celled variety. Another interesting feature is the presence of small and large cysts. Even a casual examination of the smaller variety makes it certain that their origin can be attributed to dilatation of the epithelial tubules. The larger cysts, however, are aggregated in areas where the general appearance resembles that of a cavernous angioma, the individual compartments being separated by rather cellular connective tissue, the lining being formed by a single layer of flattened endothelial-like cells. Although some of these contain red blood cells most of them are filled either by a homogeneous mass that takes the eosin stain strongly, or by spheroidal bodies that may possibly be the result of the action of the fixative. That the cysts lined by endothelial-like cells owe their origin to the gland tubules seen elsewhere in the specimen is shown by the presence of cysts of an intermediate type characterized by an irregularly shaped branching element into which papillary projections clothed in part by flattened endothelial-like cells and in part by typical cuboidal cells are found in large numbers. Marked necrosis is seen in most of the tissue.

"Diagnosis—Mixed tumor of the type described by Wilms', and of not uncommon occurrence in the kidney."

It seems to the writer always more satisfactory to publish a final report of cases like the foregoing at the time when death is the outcome, as it always is sooner or later in such lesions.

45 West Ninth Street.

Pathology of Chlorosis.—U. Archangeli advances the theory that chlorosis results from an intoxication caused by the internal secretion of the corpus luteum which, on account of uterine insufficiency, is not sufficiently eliminated. Chlorosis is accompanied by several symptoms that are similar to those which women experience before and during the menstrual period, especially when it is delayed, absent, or increased. The anemia is only a part of its clinical picture. Hypoplasia of the uterus and ovaries is an associated condition. The effect of ovarian castration in animals varies with the age of the animal, no anemia being produced in adults and a slight anemia being produced in the young. The reason why iron improves this condition is not that it stimulates the formation of red blood corpuscles, but that it neutralizes the intoxication.—*Rivista Ospedaliera.*

PEDIATRIC MEMORANDA.

TETANISM.

By HERMAN B. SHEFFIELD, M.D.,

NEW YORK.

THE term "Tetanism" is intended to denote a peculiar form of more or less *continuous* muscular hypertonicity occasionally observed in marantic infants under three months of age. I have been watching this group of cases for several years and am thoroughly convinced that it represents a typical symptom-complex based upon a distinct pathological entity entirely apart from any of the different forms of spasmophilia thus far described. It is almost invariably associated with faulty assimilation of the food,—be this due to faulty feeding, intestinal tuberculosis, or syphilis,—and is most probably the result of intestinal autointoxication. When I first described this condition* I was under the impression that it occurred only in bottle-fed babies. I have since learned, however, that breast-fed infants are occasionally affected with it as well.

The case here recorded was the third living child of healthy German parents. She weighed six pounds at birth and seemed free from any constitutional affections. Following the abominable, but generally accepted, rule, the baby was put to the breast *every two hours*—awake or asleep. It did well for the first few days, but as the mother's milk supply became abundant, it soon began to vomit, especially after each nursing, and to suffer from constipation and colic. As usually the baby's crying was attributed to hunger, and hence the nursing

Fig. 1.—During acme of the spasm.

time prolonged, and the more it nursed the more it cried, and *vice versa*. Home remedies and medicines failed to improve the child's condition, so that when at eight weeks of age it came under my observation, it was a mere skeleton, weighing a little over three and a half pounds. The face was senile, its muscles were contracted, and the jaws were tightly set together requiring considerable manual force for their separation. During the acme of the spasm

Fig. 2.—During partial relaxation of the spasm.
